10 Herein we present the Energy Balance Model – Kalman Filter (EBM-KF), a hybrid model
11 of the global mean surface temperature (GMST) and ocean heat content anomaly (OHCA). It
12 combines an energy balance model with parameters drawn from the literature and a statistical
13 extended Kalman filter assimilating observed and/or earth system model-simulated GMST &
14 OHCA. Our motivation is to create an efficient and natural estimator of the climate state and
15 its uncertainty. Our emulator is tied to the immediate physical rationale of an energy budget,
16 benefits from the mathematical similarities between an energy balance model and a Kalman
17 filter, and allows access to proven methodologies for parameter estimation and uncertainty
18 quantification. This synthesis is straightforward because climate models and historical
19 records of GMST and OHCA follow nearly Gaussian distributions. We illustrate the
20 advantages of this approach with four applications: 1) EBM-KF generates an estimate similar
21 to the 30-year time-averaged climate state 15 years sooner. 2) EBM-KF conveniently
22 assesses annually the likelihood of crossing a policy threshold, e.g., 2 °C over preindustrial.
23 3) The EBM-KF is also accurate at inferring the behavior of an entire climate model large
24 ensemble using only one or a few ensemble members. 4) The EBM-KF is sufficiently fast to
25 allow repeat sampling from non-Gaussian probabilistic futures, e.g., the impact of rare but
26 significant events such as future volcanic eruptions. This sampling with the EBM-KF better
27 determines how future volcanism may affect when policy thresholds will be crossed and what
28 a larger-than-large ensemble including future intermittent volcanism would reveal.

29

30

SIGNIFICANCE STATEMENT

31 The overall shape of the Earth's historical climate over the past 150 years can be
32 explained by a thermal/radiation physics equation involving 17 constants, atmospheric CO₂,
33 and volcanic eruptions. Global mean surface temperature measurements vary around this
34 climate state within a consistent normal distribution. This physics equation and statistical
35 depiction allowed us to construct a quick, simple model that can estimate the uncertainty in
36 Earth's current climate and aid in policy discussions and reduce ensemble modeling costs.

37

38 **1. Introduction**

39 What is the uncertainty in Earth's climate? From a measurement standpoint, this issue was
40 resolved many decades ago. The instantaneous measurement of global mean surface
41 temperature (GMST) is currently performed with average precision of 0.05°C (max 0.10°C)
42 via arrays of infrared-sensing satellites and ground stations (Susskind, Schmidt et al. 2019),
43 both these datasets extend back to 1981 (Merchant, Embury et al. 2019), and the yearly
44 fluctuation is easy to smooth with a running annual average. However, this GMST still has
45 significant dynamical and random stochasticity, from processes like the 2-7 year quasi-
46 periodic El Nino events (Hu and Fedorov 2017) and volcanic eruptions that intermittently
47 affect climate for 1-2 years (Soden, Wetherald et al. 2002). True measurement errors also
48 arise from sparse or inconsistently calibrated historical data and paleoproxies (Carré, Sachs et
49 al. 2012; Emile-Geay, McKay et al. 2017; Kaufman, McKay et al. 2020; McClelland, Halevy
50 et al. 2021). Internal variability dominates over climate-forced variability in most short-term
51 signals, both in climate simulations and reality (Kirtman, Power et al. 2013; Marotzke and
52 Forster 2015; Gulev, Thorne et al. 2021; Lee, Marotzke et al. 2021). By “simulations”, we
53 refer to computationally expensive global coupled models (and occasionally to
54 numerical weather model predictions). Variables other than GMST reveal steadier warming,
55 such as Ocean Heat Content Anomaly (OHCA) where >90% of the anthropogenic energy
56 anomaly is found ((Gulev, Thorne et al. 2021); Fox-Kemper et al. 2021;(Cheng, Trenberth et
57 al. 2017)). Even radical reductions in global CO₂ emissions may not show an identifiable
58 impact on GMST over a time scale of a few years (Szopa et al. 2021), posing a challenge for
59 policy and assessment.

60 In 1935 the World Meteorological Association began reporting the "standard climate
61 normal" as surface temperature averages of over an interval of 30 years ($\overline{_{30}T}$, starting with
62 1901-1930). A 30-year window was chosen to minimize most internal fluctuations (such as
63 El Nino) and short-term forcings such as single volcanoes (Guttman 1989). Fig. 1 shows this
64 metric and emphasizes the 30-year span over which the average is taken. To generate
65 continuous estimates of the climate, this 30-year average can be updated annually rather than
66 decadal, forming a running mean (Supp. Fig. 2b). While standard climate normals and
67 running means are straightforward and widely accepted definitions of climate, they involve
68 lag: the most current 30-year average necessarily describes the average climate state of Earth
69 15 years ago. Moreover, anthropogenic climate change distorts standard statistical metrics:
70 most of the variance in recent 30-year periods derives from the trend rather than internal
71 variability. Averaging filters (such as a running mean) remove high-frequency signals that

72 reflect year-to-year variations in global weather, as do other statistical approaches better-
 73 suited to removing frequencies above a particular cutoff (Smith 2003). The anthropogenic
 74 change beginning in the mid-1960s in Fig. 1 is similarly preserved by moving averages
 75 (running mean) or any lowpass filter / smoother. Example applications to GMST of
 76 statistical, as opposed to physical, filters commonly used in climate analysis are shown in
 77 supplemental Section B (Supp. Fig. 2, 3).

78

79 Fig. 1: Illustration of Standard Climate Normals (blue horizontal lines in 10-year overlapping
 80 bins) as applied to the HadCRUT5 GMST dataset (grey dots) (Morice, Kennedy et al. 2021).
 81 Twice the standard deviation ($\pm 2\sigma$) is plotted above and below (cyan error bars), and two
 82 standard errors are also plotted (green rectangles). Note how standard deviations widen in
 83 recent decades due to the anthropogenic trend.

84

85 Policy goals often are framed via climate change staying below a particular policy
 86 threshold (e.g., 1.5°C or 2°C above pre-industrial conditions in the Paris Agreement). Using a
 87 30-year mean brings difficulty in determining exactly when or if a policy threshold is crossed
 88 ((Lee, Marotzke et al. 2021)). Policy thresholds are not system thresholds — temperature
 89 “tipping” points when the dynamics of the climate system are reorganized often abruptly or
 90 irreversibly — and so they are subject to definitional uncertainty. Relatedly, magnitudes and
 91 uncertainty ranges are meaningful only under specific averaging windows, e.g., “GMST
 92 increased by 0.85 [0.69 to 0.95] °C between 1850–1900 and 1995–2014 and by 1.09 [0.95 to

93 1.20] °C between 1850–1900 and 2011–2020.” (Gulev, Thorne et al. 2021). Tools for
94 assessing if a policy threshold has been crossed yet will be useful as these policy targets
95 approach.

96 To overcome limited sampling of the real world, many climate studies instead investigate
97 the climate system within globally coupled climate simulations ("coupled" refers to coupled
98 sub-models, principally the atmosphere and ocean) or earth system models: ESMs (Meehl,
99 Moss et al. 2014). Typically, these simulations are forced using historical records and a range
100 of scenarios for future projections (including CO₂ emissions, other pollutants, land use, and
101 volcanic eruptions; (Lee, Marotzke et al. 2021)). The chaotic nature of weather and varying
102 initial conditions produce an ensemble of identically-forced simulations that explore the span
103 of outcomes consistent with forcing, such as for the CESM2 Large Ensemble (Rodgers, Lee
104 et al. 2021), abbreviated here as LENS2. Unfortunately, each ensemble member simulation is
105 computationally expensive and does not accurately or transparently reflect the real climate
106 system, but only one realization of it including model errors.

107 Therefore, we sought an efficient and natural estimator of the uncertainty in the climate
108 state: the EBM-KF. We combined a nonlinear energy-balance difference equation (EBM) and
109 a statistical observation equation (KF) that brings in the available measured GMST and
110 OHCA data, yielding a hybrid physical model – statistical filter. This data-driven climate
111 emulator (Forster, Storelvmo et al. 2021) by construction inherits benefits from its chosen
112 constituent models and is vastly more efficient than ensembles of ESMs that provide similar
113 information. Our emulator is interpretable as a global energy budget, benefits from the
114 mathematical similarities between an energy balance model and a Kalman filter, and allows
115 access to proven methodologies for parameter estimation (Chen, Heckman et al. 2018; Zhang
116 and Atia 2020) and uncertainty quantification (Sætrum and Omre 2013). No part of this
117 emulator was empirically fit to the climate record: 12 of the 17 parameters within the energy-
118 balance equation were obtained directly from literature estimates, whereas the remaining 5
119 parameters are inferred indirectly from assumed pre-industrial climate equilibrium and
120 literature estimates of climate sensitivities. Our simple iterative energy-balance model has
121 good skill at predicting the GMST and OHCA despite being by itself "blind" to all
122 measurements (i.e., a “forward” model in numerical weather prediction terminology). The
123 statistical component is an extended Kalman Filter, which allows for incorporation of current
124 measurements to "course-correct" under a well-understood mathematical framework. Noise
125 covariance matrices within this statistical observation equation were constructed such that the

126 “climate state” most closely resembles the 30-year running mean of GMST and OHCA.
 127 Hybridizing these two components yields statistical distributions of uncertainty from internal
 128 variability and a physical rationale for the filtered current climate state.

129 After it is introduced in Section 2, the EBM-KF is illustrated on four applications to
 130 historical and future climate. 1) Section 3a shows that it estimates the 30-year mean climate
 131 normal every year, including the latest observations and without lag. 2) Section 3b shows
 132 how it can be used to assess the probability that a policy threshold has been crossed in any
 133 particular year. 3) Section 3c shows how it can be used to estimate the ensemble mean of an
 134 ESM Large Ensemble from only one ensemble member. 4) Section 3d shows that the EBM-
 135 KF is sufficiently fast to allow high-density sampling of non-Gaussian probabilistic futures,
 136 e.g., directly sampling over highly intermittent distributions of future volcanic eruptions.
 137 Section 4 discusses these results, some cautionary remarks, opportunities for extension, and
 138 application to policymaking. Section 5 concludes. Extensive appendices and supplementary
 139 material convey additional detail. Throughout, a 2σ or approximately 95% confidence
 140 interval is used, indicating the *extremely likely* range in IPCC terminology.

141 2. Methods

142 a. Energy-Balance Model

143 The energy-balance model is constructed by envisioning a uniform planet and capturing
 144 the principal atmospheric and surface energy fluxes (Budyko 1969; Sellers 1969). This model
 145 is "blind" with respect to observations and is inspired by other energy-budget models
 146 illustrating quantitative skill (Hu and Fedorov 2017; Kravitz, Rasch et al. 2018) at
 147 approximating both GMST and the 30-year running mean. The model includes two layers: a
 148 surface layer including thermally active soil and 86m of ocean water depth (with temperature
 149 approximating GMST), and a deep ocean layer reaching (1141+86)m depth that exchanges
 150 energy (part of OHCA) with the surface layer ((Gregory 2000)). These depths are chosen
 151 based on heat capacity estimates and are unrelated to observational oceanographic traditions.
 152 The overall energy fluxes into the model layers are as follows:

$$153 \frac{T_{n+1}-T_n}{k} C_{\text{surf}} = G_0^* \tilde{d}_n * f_{\alpha A}(T_n) * f_{\alpha S}(T_n) - j^* * \tilde{g}_n * f_{H_2O}(T_n) - \gamma * (T_n - \theta_n - \zeta) \quad (1)$$

$$154 \frac{\theta_{n+1}-\theta_n}{k} C_{\text{deep}} = \gamma * (T_n - \theta_n - \zeta) \quad (2)$$

$$155 H_n = (T_n - T_{1850}) * C_{\text{surf}0} + (\theta_n - \theta_{1850}) * C_{\text{deep}} \quad (3)$$

156 T_n is GMST in calendar year n (e.g. 2000), whereas θ_n is the potential (or conservative)
 157 temperature of the deep ocean in that same year, and H_n is OHCA including both that deep
 158 ocean layer and the surface ocean (McDougall, Barker et al. 2021). Closely related variables
 159 to GMST, such as Global Surface Air Temperature (GSAT), differ only from GMST by
 160 measurement and slightly in uncertainty (by less than our confidence intervals) but not
 161 systematically (Gulev et al. 2021). For example, GMST is easier to measure in the past, while
 162 GSAT is more easily found from future model projections, so here we do not distinguish
 163 between them. The time unit k is 1 year, matching the time step of this iterative difference
 164 equation model. On the right side of the equation, both the shortwave radiative flux and
 165 longwave radiative flux take the same form: (source G_0^* , j^*) * (prescribed attenuation: \tilde{d}_n , \tilde{g}_n
 166) * (attenuation function with feedback: $f_{\alpha}(T_n)$). The overall surface heat capacity, C_{heat} , is
 167 known with low precision: reported values (from modeling / timeseries analysis) are 17 ± 7
 168 $\text{W (year) m}^{-2} \text{K}^{-1}$, (Schwartz, 2007). G_0^* is the extraterrestrial radiance at 340.1 W/m^2
 169 (optionally allowed to vary from 340.06 to 340.48 from Coddington (2017): an insignificant
 170 input to the climate system). \tilde{d}_n is the prescribed shortwave radiation attenuation due to
 171 volcanic dust (values from Sato (1993), Vernier (2011), and NASA (2018)), $f_{\alpha A}(T_n)$ is the
 172 additional atmospheric shortwave attenuation due to cloud albedo incorporating
 173 anthropogenic cloud-nucleating aerosols AC_n , while $f_{\alpha S}(T_n)$ is the surface shortwave
 174 attenuation due to ground albedo. Infrared heat emitted from the surface is $j^* = \sigma_{\text{sf}} T_n^4$, the
 175 ideal Planck black body radiation. \tilde{g}_n is the prescribed longwave attenuation due to CO_2 and
 176 other greenhouse gasses, and $f_{\text{H}_2\text{O}}(T_n)$ is the additional atmospheric longwave attenuation due
 177 to water vapor and other gasses parameterized as a function of GMST. Both \tilde{d}_n and \tilde{g}_n are
 178 taken from Forster et. al. (2023). Several of these terms were defined to satisfy the constraints
 179 of the climate feedbacks presented in the IPCC AR6 (Forster et al. 2021; particularly Table
 180 7.10), and all coefficients were based on observational and modelling literature values,
 181 typically with energy fluxes measured from satellites and temperature feedback coefficients
 182 determined from model results (full derivation in Appendix A). Because the Planck radiation
 183 requires absolute temperatures, we use degrees Kelvin in model calculations and convert to
 184 $^{\circ}\text{C}$. OHCA is also approximately convertible to thermosteric sea level rise, via the 0.0121
 185 cm/ZJ factor from analysis of 1995 to 2014 (AR6 cross-chapter box 9.1). With this factor, the
 186 estimated thermosteric sea level rises we find are consistent with observations and
 187 projections; the EBM also estimates sea level rise in this manner (Fox-Kemper, Hewitt et al.
 188 2021). The two negative albedo attenuations $f_{\alpha A}(T_n) * f_{\alpha S}(T_n)$ are expressed relative to

189 287.5K (14.35°C), the temperature in 2002. $\zeta = 10^\circ\text{C}$ is an equilibrium temperature
 190 difference between the surface layer and deep ocean, arising because the global ocean is
 191 thermally stratified. γ is the thermal conductivity between layers of the ocean, taken from
 192 Geoffroy (2013) to be 0.67 W/m²/K, the average from the CMIP5 models. The form of this
 193 parameterization of deep ocean temperature exchange follows recent work in emulating
 194 ocean heat uptake, ignoring “efficiency factor” heat loss (Gregory 2000; Winton, Takahashi
 195 et al. 2010; Geoffroy, Saint-Martin et al. 2013; Emile-Geay, McKay et al. 2017; Palmer,
 196 Harris et al. 2018).

197 Measurements of temperature were obtained as relative anomalies (GMST from
 198 HadCRUT5 (Morice, Kennedy et al. 2021), OHCA from Zanna et al. (2019)), and the model
 199 also assumes a preindustrial (1850) GMST of 286.7K (13.55°C), which allows the 1960-1990
 200 "standard climate normal" of GMST HadCRUT5 measurements to fall within the range
 201 (13.7°C - 14°C) given by Jones and Harpham (2013). This choice is important regarding the
 202 determination of many nonlinear feedback functions and coefficients affecting the surface
 203 layer (eq. 5 below), particularly with respect to the Planck feedback. Similarly, the deep
 204 ocean temperature was chosen to be 276.65K in 1850, such that current deep ocean potential
 205 temperatures are about 3.8°C, but this choice only sets the equilibrium temperature difference
 206 ζ , and the chosen energy balance model is linear with respect to θ_n .

207 Overall, the blind (forward) energy-balance model (orange dashed line in Figure 2) has 3
 208 yearly forcing inputs ($[\text{eCO}_2]_n$, AOD_n , AC_n , and optionally G_0^*) and 17 irreducible
 209 parameters (including 1 inferred exponent, 4 inferred β coefficients, 3 heat capacities, and 3
 210 reference temperatures). The deep ocean potential temperature θ_n is recalculated at each time
 211 step from the GMST (T_n) and the OHCA (H_n), and then these two terms are updated:

$$212 \quad \theta_n = (H_n - (T_n - T_{1850}) * C_{\text{surf}0}) / C_{\text{deep}} + \theta_{1850} \quad (4)$$

$$213 \quad T_{n+1} = T_n + \frac{G_0^* 0.758 * 9.068}{C_{\text{surf}} (AOD_n + 9.73)} \left(1 + \beta_2 (T_n - 287.5) + \frac{AC_n - AC_{2002}}{G_0^* \overline{d_{2002}} 0.834} \right) \left(1 + \beta_3 (T_n - 287.5) \right)$$

$$214 \quad - \frac{\sigma_{sf} \beta_1}{C_{\text{surf}}} (T_n)^{2.39} (1 - \beta_0 \log_{10}([\text{eCO}_2]_n)) - \frac{\gamma}{C_{\text{surf}}} (T_n - \theta_n - \zeta) \quad (5)$$

$$215 \quad H_{n+1} = (T_{n+1} - T_{1850}) * C_{\text{surf}0} + \gamma * (T_n - \theta_n - \zeta) + (\theta_n - \theta_{1850}) * C_{\text{deep}} \quad (6)$$

216
 217 All coefficients are constant in time, and assume the temperatures are in Kelvin, eCO₂
 218 concentrations are in ppm, aerosol optical depth is unitless, and both AC_n and the optional

219 G_0^* are in W/m^2 . For this model, the OHCA (H_n) is calculated in units of $W \cdot year/m^2$ on an
220 average of the Earth's surface, and then converted to ZJ within the ocean by multiplying by a
221 factor of $11.42 = 3.154e7 \text{ s/year} * 5.101e7 \text{ m}^2 / \text{Earth surface} * 0.71 \text{ ocean/surface}$. This time-
222 step function (4-6) and its partial derivative (see Appendix A4) will become critical parts of
223 the Kalman filter: (9, 10) below.

224 This EBM model had good skill at predicting the GMST with an $R^2 = 0.90$ when
225 compared to the HadCRUT5 GMST timeseries (Morice, Kennedy et al. 2021), and OHCA
226 with an $R^2 = 0.91$ when compared with the inferred temperature history (Zanna, Khatiwala et
227 al. 2019), as is demonstrated by the dashed orange lines in Fig. 2. The forward EBM has a
228 comparably high correlation ($R^2=0.89$) with the 30-year running mean (i.e., the climate
229 normal) of the HadCRUT5 GMST, indicating that this forward energy balance model also
230 has skill in reproducing the climate state as determined by standard approaches, with
231 departures due to volcanic eruptions. Residuals in the GMST record from either the 30-year
232 running mean or the EBM are approximately Gaussian (small bias and skewness – see Supp.
233 Fig. 4) and thus this “weather” or “noise” is amenable to treatment by the Kalman filter
234 framework (see next section 2b). These residuals have a non-Gaussian kurtosis to
235 accommodate the measurement uncertainty, as is discussed in section 3a in relation to Fig. 3
236 & 4. The Fig. 2 comparisons were made without any assimilated data, illustrating that the
237 EBM physics alone has skill in reproducing aspects of the GMST & OHCA records. Tuning
238 the EBM parameters may further improve skill, but the EBM is only the forward component
239 of the hybrid data-assimilating Kalman Filter model described in the next section. The
240 combined system is the focus of this paper.

241 *b. EBM-Kalman Filter: A Weighted Average of Energy Balance and Measurements*

242 While similar algorithms were developed in the 1880s by Thorvald Nicolai Thiele
243 (Lauritzen 1981; Lauritzen and Thiele 2002), Kalman filtering rose to prominence due to its
244 use in the Apollo navigation computer as proposed by Ruslan Stratonovich (1959; 1960),
245 Peter Swerling (1959), Rudolf E. Kálmán (1960), Richard S. Bucy (1961), and implemented
246 by Stanley Schmidt (1981). Versions of this statistical filter are universally used in aerospace
247 guidance systems (Grewal and Andrews 2001), aspects of numerical weather prediction
248 (Houtekamer and Mitchell 1998; Kalnay 2002; Annan, Hargreaves et al. 2005), and recently
249 popularly as Ensemble Kalman filters (which use a Monte Carlo approximation via
250 simulations in high-dimensional space, see below). Ensemble Kalman filters (not to be

251 confused with extended Kalman filters, the subject of this paper) have been instrumental to
252 20th century reanalysis (Compo, Whitaker et al. 2011) and last millennium reanalysis projects
253 (Hakim, Emile-Geay et al. 2016) of global atmospheric circulation. In the Ensemble Kalman
254 Filter, observations sample the full gridded weather patterns (a space with hundreds to
255 millions of dimensions) within an ensemble of ESMs. Despite the success of Ensemble
256 Kalman filters, *extended* Kalman filters are ineffective as the sole data assimilation tool for
257 atmospheric weather patterns (Bouttier 1996). While many local weather processes do not
258 sample from a Gaussian distribution, the central limit theorem states that taking the average
259 of many independent non-Gaussian samples will produce a mean that approximates a
260 Gaussian distribution. This is the case for both annual GMST (Montgomery and Runger
261 2013), which is the average of many non-Gaussian regional and daily weather patterns
262 (Quevedo and Gonzalez 2017). Likewise, while annual OHCA is largely constrained by the
263 subtropical pycnocline depth (Newsom, Zanna et al. 2023), it too is comprised of numerous
264 regional and seasonal patterns (Hummels, Dengler et al. 2013; Cheng, Trenberth et al. 2017;
265 Huguenin, Holmes et al. 2022). In this case of *global* GMST and OHCA, an extended
266 Kalman filter works because both measurement and dynamical noise are approximately
267 Gaussian (to be verified in Section 3), and the energy-balance equation (Section 2a) has a
268 continuous and bounded gradient (see Appendix A4), so it can be locally linearized. Careful
269 construction of the EBM with T^2 in the shortwave term and $T^{2.39}$ in the counteracting
270 longwave term in (Eqs. 1 and 5) ensures the derivative (A37-41) does not change
271 significantly over the relevant range of temperatures (286K - 291K), effective CO₂
272 concentrations (278 - 2000 ppm), AOD (0 - 0.15), and \tilde{q}_n anthropogenic cloud forcing (-1 - 0
273 W/m²). This approximate linearity means that more complex realizations of the Kalman
274 filter, particularly the Unscented Kalman Filter (Julier and Uhlmann 1997; Wan and Van Der
275 Merwe 2000) are not necessary (see Supplement Section C). Thus, the EBM-Kalman Filter
276 (EBM-KF) can be built from an extended Kalman Filter combined with an Energy Balance
277 Model.

278 In-depth derivations and tutorials for constructing Kalman filters have been published
279 elsewhere (Miller 1996; Lacey 1998; Särkkä 2013; Benhamou 2018; Youngjoo and
280 Hyochoong 2018; Ogorek 2019). Here we describe enough for basic intuition, although page
281 281 of Kalnay (2002) may be more familiar. Initially, there is some estimated *state vector*
282 (GMST and OHCA within this paper) $\hat{\mathbf{x}}_{n-1}$ and a Gaussian uncertainty envelope around this
283 vector defined by a *state covariance matrix* \mathbf{P}_{n-1} . These can be projected *a priori* (without

284 observations) into the future using a *dynamic model matrix* Φ (for our climate system this is
285 extended to the function F (7), which is the forward energy balance model (3)-(6)). The
286 projected covariance enlarges by an additional assumed *model error covariance* \mathbf{Q} , yielding
287 $\mathbf{P}_{n|n-1}$ (8). To arrive at *a posteriori* (including observations) information a *measurement vector*
288 \mathbf{y}_n is considered (9). The probabilistic range of discrepancies between $\Phi\hat{\mathbf{x}}_{n-1}$ and \mathbf{y}_n is given
289 by the *innovation covariance matrix* \mathbf{S}_n , which is the sum of $\mathbf{P}_{n|n-1}$ and an assumed
290 *measurement covariance* \mathbf{R} (10). The *a posteriori estimate* for the state $\hat{\mathbf{x}}_n$ is found by taking
291 a weighted average of $\Phi\hat{\mathbf{x}}_{n-1}$ and \mathbf{y}_n (12), with the weight on \mathbf{y}_n given by $\mathbf{P}_{n|n-1}(\mathbf{S}_n)^{-1}$, a product
292 known as the *Kalman gain* (11). To reflect the greater certainty in the state vector because of
293 this correction, \mathbf{P}_n , the *a posteriori covariance matrix*, is $\mathbf{P}_{n|n-1}$ shrunk by a factor of \mathbf{I} -minus-
294 the-Kalman-gain (13). Within the context of Bayesian probability, the *prior distribution* is
295 given by projecting $N(\hat{\mathbf{x}}_{n-1}, \mathbf{P}_{n-1})$ into the future using Φ , which is multiplied by the support
296 of \mathbf{y}_n to give a *posterior distribution* $N(\hat{\mathbf{x}}_n, \mathbf{P}_n)$.

$$297 \quad \Phi_n = \left. \frac{\partial \mathbf{F}(\mathbf{x}; u_n)}{\partial \mathbf{x}} \right|_{\mathbf{x}=\hat{\mathbf{x}}_{n-1}} \quad \text{linearization at timepoint } n \quad (7)$$

$$298 \quad \begin{cases} \mathbf{x}_n = \mathbf{F}(\mathbf{x}_{n-1}; u_n) + w_n \\ \mathbf{y}_n = \mathbf{x}_n + v_n \end{cases} \quad \begin{array}{l} \text{dynamic model, error: } \mathbf{Q} = \text{Cov}(w_n) \\ \text{measurements, error: } \mathbf{R} = \text{Cov}(v_n) \end{array} \quad (8)$$

$$299 \quad \hat{\mathbf{x}}_{n|n-1} = \mathbf{F}(\hat{\mathbf{x}}_{n-1}; u_n) \quad \text{a priori estimated state projection} \quad (9)$$

$$300 \quad \mathbf{P}_{n|n-1} = \Phi_n \mathbf{P}_{n-1} (\Phi_n)^T + \mathbf{Q} \quad \text{a priori state variance projection} \quad (10)$$

$$301 \quad \mathbf{c}_n = \mathbf{y}_n - \hat{\mathbf{x}}_{n|n-1} \quad \text{innovation residual} \quad (11)$$

$$302 \quad \mathbf{S}_n = \mathbf{P}_{n|n-1} + \mathbf{R} \quad \text{innovation covariance} \quad (12)$$

$$303 \quad \mathbf{K}_n = \mathbf{P}_{n|n-1} (\mathbf{S}_n)^{-1} \quad \text{Kalman gain} \quad (13)$$

$$304 \quad \hat{\mathbf{x}}_n = \hat{\mathbf{x}}_{n|n-1} + \mathbf{K}_n \mathbf{c}_n \quad \text{a posteriori estimated state} \quad (14)$$

$$305 \quad \mathbf{P}_n = (\mathbf{I} - \mathbf{K}_n) \mathbf{P}_{n|n-1} \quad \text{a posteriori state covariance} \quad (15)$$

306 For the climate state, we consider a two-dimensional pair: [GMST, OHCA]. If \mathbf{y}_n is an
307 indirect measurement of the state vector \mathbf{x}_n (for instance GMST and OHCA approximated by
308 a set of point measurements across the globe), an observation (a.k.a. emission) matrix \mathbf{H}
309 further complicates the procedure. Here we consider only “observations” of GMST and
310 OHCA making mapping and interpolation errors implicit and the observation matrix $\mathbf{H} = \mathbf{I}$
311 $= \mathbf{1}$, and we use italics to indicate this choice.

312 The abstract unknown state x_n is the climate state of GMST and OHCA, filtering out
313 weather and internal variability. The noisy measurements $\mathbf{y}_n = [Y_n, \psi_n]$ are the yearly time

314 series of GMST and OHCA, and $\hat{\mathbf{x}}_n = [\hat{T}_n, H_n]$ is the estimate of the unknown 2-dimensional
 315 climate state, both expressed in degrees Kelvin. The energy-balance model F (8) governing
 316 \hat{T}_n is nonlinear (with T^2 and $T^{2.385}$ terms due to albedo and Planck feedbacks), which
 317 necessitates an extended Kalman filter: the *a priori* estimated state projection (9) is given by
 318 (3,5) above and Φ_n for the *a priori* state covariance projection (10) is a time-varying
 319 linearization (4,6). This energy-conserving difference equation thus resembles a first-order
 320 Taylor series approximation of a differential energy-balance model (if discretization errors
 321 are considered part of the tendency), or the integral form of a conservative discretization in
 322 time (if shortwave and longwave fluxes are taken as a model for their time-integrated value),
 323 and the Kalman Filter re-approximates a GMST and OHCA climate state every year. The
 324 initial estimated state uncertainty, P_0 , is intentionally overestimated at $\begin{bmatrix} 1K & 1 \\ 1 & 20 \frac{W yr}{m^2} \end{bmatrix}$ and
 325 then P_n rapidly converges (within ~ 10 years) in the EBM-KF to $\begin{bmatrix} 0.0013K & 0.041 \\ 0.041 & 4.6 \frac{W yr}{m^2} \end{bmatrix}$, and
 326 then continues to slowly shrink with time as more accurate measurements are made. The
 327 extended Kalman Filter implicitly assumes that Gaussian “model” noise is added to this
 328 climate state at each time step, and additional Gaussian “measurement” noise causes the
 329 climate state to emit annual weather.

330 The EBM-KF climate state $\hat{\mathbf{x}}_n$ and state covariance P_n only access information from
 331 the measurements taken prior to and at year n : $\{y_{1850}, y_{1851}, \dots, y_n\}$. This past-to-present
 332 Kalman Filter (7-15) can be extended into a RTS smoother (Rauch, Tung et al. 1965) by
 333 additional steps (see Supp. Section A), which melds information from all measurements in
 334 the time window $\{y_{1850}, y_{1851}, \dots, y_{2022}\}$ into each re-estimated state $\hat{\hat{\mathbf{x}}}_n$ and state covariance
 335 $\hat{\hat{P}}_n$ by running backward from the latest EBM-KF state estimates ($\hat{\mathbf{x}}_{2022}$ and P_{2022}). In the 1850
 336 to present application, this extension has little effect on $\hat{\mathbf{x}}_n$ (see Supp. Fig. 1), but there is
 337 more certainty in this state: $\hat{\hat{P}}_n$ shrinks relative to P_n (see Supp. Fig. 10) by factors of 2.25 and
 338 2.84 for the GMST and OHCA components respectively.

339 In summary, the extended Kalman filter projects forward one year into the future
 340 based on the unbalanced fluxes of the energy balance model equation, and then takes a
 341 weighted average of this projection with the annual GMST measurement (the data
 342 assimilation increment). Thus, even though the EBM conserves energy (by construction), the
 343 combined EBM-KF does not, unlike other alternative data assimilation approaches (Wunsch

344 and Heimbach 2007). The state estimates from this EBM-KF (in navy blue in Fig. 2) almost
345 always lie between the blind EBM (in dashed orange in Fig. 2) and the annual temperature
346 measurements (scattered gray dots in Fig. 2), a corrective effect that can be seen most clearly
347 with the OHCA measurements in Fig 2b after 1940. It is possible for the EBM-KF state
348 estimates to escape these bounds for a short time, for instance from 1937 to 1939 in Fig. 2a or
349 after 2007 in Fig 2b. Both the “blind” EBM predictions $[\tilde{T}_{n+1}, \tilde{H}_{n+1}] = \mathbf{F}(\tilde{T}_n, \tilde{H}_n, u_n)$ and
350 EMB-KF state estimates $\hat{\mathbf{x}}_n = [\hat{T}_n, \hat{H}_n]$ dip down with each major volcanic eruption within
351 the AOD record (see Fig. 9). This is because while EBM within the extended Kalman Filter
352 can alter the energy flux via net-negative feedbacks, energy imbalances do not resolve within
353 a single year due to heat capacity (especially large for the deep ocean), and new observations
354 change the weighted average minimally.

355

356 Fig. 2: Behavior of the EBM-KF state in relation to blind EBM projections and the stochastic
 357 measurements of GMST and OHCA. Panel a) shows GMST prediction and b) the OHCA
 358 prediction. The blind model (dashed orange) and Kalman filter state estimate (navy blue) use
 359 EBM dynamics to project from the previous state to the current state, but the state estimate
 360 also assimilates observations (grey dots; GMST from HadCRUT5 and from Zanna et al.
 361 (2019)).

362

363 *c. Selection of Model Uncertainty and Time-Varying Measurement Uncertainty*

364 Fig. 2 also demonstrates the accuracy associated with each of the temperature
365 measurements. The uncertainty in the climate state P_n automatically responds to unexpected
366 values of the measured temperature (Wunsch 2020). The HadCRUT5 GMST decreases in
367 standard deviation from 0.079K in the 1850-1879 window to 0.017K in the 1990-2019
368 window (Morice, Kennedy et al. 2021), primarily reflecting a lack of observations in the
369 Southern hemisphere before the satellite age. The inferred deep ocean heat content taken
370 here from a hybrid model-observation reconstruction (Zanna, Khatiwala et al. 2019) has a
371 very wide confidence interval before the introduction of modern sampling, especially Argo
372 floats. We choose to use the Zanna et al. (2019) hybrid product due to its long duration of
373 OHCA estimates (based on surface forcing in early years) rather than the shorter direct
374 measurement products (e.g., (Ishii, Fukuda et al. 2017)), although as previously mentioned
375 both could be assimilated simultaneously within EBM-KF if desired. The EBM-KF
376 incorporates the known uncertainty in the HadCRUT5 measurements of GMST and the
377 OHCA reconstruction. The total measurement covariance R is composed of two components:
378 the time-varying physical measurement uncertainty $R_{\text{var}}(n)$, and the constant uncertainty
379 reflecting internal variability due to chaos R_{const} . We assume that $R_{\text{var}}(n)$ is diagonal and
380 simply sum the two variance matrices to obtain a time-varying value of $R_n = R_{\text{var}}(n) + R_{\text{const}}$.

381 The realization of the EBM-KF shown in Fig. 2 has a measurement uncertainty R_{const}
382 in (10) that is constant and based on the [HadCRUT5, ocean potential temperature] residual
383 co-variance with respect to their 30-year running means. In other words, we computed R_{const}
384 $= \text{Cov}(\mathbf{y}_n -_{30}\bar{\mathbf{y}}_n)$. This $R_{\text{const}} = \begin{bmatrix} 0.00102 & -0.00039 \\ -0.00039 & 0.00007 \end{bmatrix}$ may slightly underestimate the
385 covariance, as a perturbation in weather on a particular year will also cause the 30-year mean
386 to rise or fall in the same direction, shrinking the measured difference. The EBM uncertainty,
387 Q , was set to $R_{\text{const}}/30$ to emulate the 30-year running average definition of climate state
388 (Guttman 1989), thus we assume that the random noise contained within the model has a
389 variance that is $1/30^{\text{th}}$ as large as the variance in the measurements. By this simple method,
390 the data-assimilating EBM-KF is tuned to match the “standard climate normal”, as this 30-
391 year running average is everywhere a 30-member sample average with variance $1/30^{\text{th}}$ as
392 large as the annual measurements’ variance (assuming yearly anomalies are uncorrelated).
393 This variance in annual measurements arises due to chaos within the climate system, so this

394 contribution to the model and measurement uncertainty would exist even if all measurements
395 could be made with arbitrary accuracy.

396 *d. Non-Gaussian Future Projection and Sampling of Volcanic Activity*

397 Any EBM-KF can project into the future, given greenhouse gas and aerosol
398 concentrations, without any new measurements using only the forward model to obtain *a*
399 *priori* estimates (9) and (10), and then taking the *a posteriori* state and *a posteriori*
400 covariance equal to the *a priori* (projected) state and *a priori* covariance, i.e., an *a posteriori*
401 unaffected by any new observations: $\hat{\mathbf{x}}_n = \mathbf{F}(\hat{\mathbf{x}}_{n-1})$ and $\mathbf{P}_n = \Phi_n^2 \mathbf{P}_{n-1} + \mathbf{Q}$. In these projections the
402 state covariance grows linearly, but $\mathbf{Q}[0,0]$ for GMST is very small (variance $\sim 0.00034 \text{ K}^2$).
403 Over a 78-year future projection (2023-2100) the state covariance $2\sqrt{P_n}$ only grows from a 2σ
404 uncertainty of 0.0613K to between 0.0726K and 0.0730K. This 18.4-19.1% increase is
405 imperceptible over the 21st century compared to the GMST dips that occur under volcanic
406 eruptions, see figure 7. In contrast, $\mathbf{Q}[1,1]$ for OHCA is much larger relative to the converged
407 state uncertainty $2\sqrt{P_n}$, and volcanoes have a negligible effect on of projected OHCA
408 trajectories. The ocean state uncertainty window $2\sqrt{P_n}$, initially at $\sim 0.0095\text{K}$ in 2023, steadily
409 balloons to $\sim 0.221\text{K}$ by 2100, an increase of 133%. The effect of volcanoes on historical state
410 (Fig. 2) and future projections (Fig. 7) is therefore worthy of specialized treatment in addition
411 to measurement uncertainty and internal chaotic variability.

412 Future projections along the shared socioeconomic pathways (SSPs) for the EBM-KF
413 also require the concentrations of greenhouse gasses including carbon dioxide ($[\text{CO}_2]_n$),
414 stratospheric aerosol optical depth due to volcanic dust and human emissions (AOD_n), and
415 reflective flux from anthropogenic clouds (AC_n). ESMs typically simulate the carbon cycle
416 and thus find CO_2 concentrations from CO_2 fluxes, but our EBM-KF doesn't have this
417 capability. Future greenhouse gas concentrations and anthropogenic cloud forcings are
418 instead taken from a conversion of anthropogenic fluxes by the MAGIC7.0 carbon cycle
419 emulator (Meinshausen, Nicholls et al. 2020), as reported by Smith (Smith, Forster et al.
420 2021). For instance, SSP1-2.6 and SSP3-7.0 are shown in Fig. 7, which flank the most likely
421 result of current environmental policies (Pielke Jr, Burgess et al. 2022). Projection of
422 anthropogenic forcings from Nazarenko et. al. (2022) using the NASA GISS ESM model
423 yielded very similar future curves (not shown).

424 Future volcanic eruptions require modeling as well. Volcanic eruptions determining
425 AOD_n are inherently stochastic, but the time intervals between eruptions can be approximated
426 using exponential distributions (Papale 2018). In standard ESMs, future volcanism is usually

427 included by a steady “background” volcanism, neglecting the exponential distribution’s
428 intermittency. Even though the EBM-KF assumes Gaussian error and thus can’t include
429 exponential distributions, it is so computationally inexpensive that it can be rerun to sample
430 over complex non-Gaussian distributions. This ability to include future volcanoes illustrates a
431 major advantage of this system: thousands of future scenario inputs can be generated and
432 utilized within minutes on a laptop, while each ESM of the LENS2 ensemble took over a
433 week to run on a supercomputer (roughly a billion times more effort per ensemble member)
434 limiting the ensemble size and thus motivating only a background constant level of
435 volcanism. No single exponential distribution fits well to the observed series of volcano
436 intervals, so an exponential mixture with two components was found to be the best fit to the
437 data using the decomposed normalized maximum likelihood (Okada, Yamanishi et al. 2020).
438 See Appendix B for further details. While these distribution approximations may be
439 improved by better volcanology, they provide reasonable future aerosol optical depths to be
440 fed into the EBM-KF.

441

442 **3. Results**

443 *a. EBM-KF Climate State (1850-Present) as an Estimator of the 30-year Running Average*

444 Fig. 3: EBM-KF and associated uncertainties. a) The EBM-KF climate state estimate (navy
 445 blue line) is drawn with a $2\sigma = 2\sqrt{P_n}$ (95% or *extremely likely*) confidence interval (light
 447 green area). Annual-mean HadCRUT5 GMST measurements are assimilated (gray dots). A
 448 2σ confidence interval (light blue) of the innovation covariance ($\sqrt{S_n}$) is drawn around the
 449 projected state estimate $\hat{T}_{n|n-1}$, showing where the Kalman filter expects the subsequent year's
 450 temperature measurement to be. b) The deviation between the projected climate state (pink)
 451 and Gaussian mixture of measurements with associated uncertainty (purple), with horizontal
 452 axis labeled with the ideal distribution from the innovation covariance. c) Quantile-quantile
 453 plot of these innovations.

454

455 A primary product of this paper is the EBM-KF climate state (Fig. 3a). Recall that the
 456 forward EBM uses published literature values: this is not an empirical fit to GMST and
 457 OHCA data. Within this Kalman filtered climate, there are two distinct Gaussian distributions
 458 relevant to climate science: the uncertainty in the current climate state, as graphed in narrow
 459 green envelope in Fig. 3a, and the uncertainty window of possible next-year GMST
 460 measurements, as graphed in the light blue wider envelope. Further examination of the
 461 difference between projected states $\hat{T}_{n|n-1}$ and *a posteriori* estimated states \hat{T}_n reveals that on
 462 an individual year basis, assimilation of the GMST measurement only shifts $\hat{T}_{n|n-1}$ by at most
 463 0.025K, compared with the standard deviation of the adjustment in \tilde{T}_n from the blind, forward
 464 model contribution of up to 0.05K per year. However, as in Fig. 2, repeated small increments

465 of this magnitude by consistently lower or higher than expected GMST measurements can
466 push \hat{T}_n away from \tilde{T}_n by as much as 0.08K over a few years. After an initial convergence
467 period of about a decade, $2\sqrt{P_n}$ slightly shrinks from $\sim 0.064\text{K}$ in the late 1800s to 0.061K in
468 the early 2000s, meanwhile $2\sqrt{S_n}$ converges from $\sim 0.28\text{K}$ to 0.215K . In net over the entire
469 time series, the measurements have nearly equal warming and cooling contributions to the
470 underlying \hat{T}_n climate state, forming the expected Gaussian distribution as demonstrated in
471 Fig 3b. The empirical projection probability distribution (a Gaussian mixture of all
472 measurement uncertainties relative to the EBM-KF predictive distribution) and ideal
473 probability distributions (the Gaussian EBM-KF predictive distribution) closely match (Fig.
474 3b), confirming that the annual measurements of GMST can be interpreted as Gaussian noise
475 around an underlying climate state approximating the "standard climate normal" 30-year
476 mean. In the quantile-quantile plot (Fig. 3c), the innovation data follows a straight line,
477 showing good support for the Kalman filter assumption of Gaussian residuals. Thus, most
478 climate state change can be explained by the literature-based blind, forward energy-balance
479 model and measurements of greenhouse gas and stratospheric aerosol concentrations,
480 consistent with recent forward-EBM applications (Hu and Fedorov 2017; Kravitz, Rasch et
481 al. 2018).

482 The EBM-KF climate state estimate over 1850 to present is not substantively different
483 from the 30-year moving average except for the impact of volcanoes. It departs from LENS
484 in the interval from 1940 – 2000 (see Supp. Fig. 2, 3, 8). On close examination, this EBM-
485 KF climate state was warmer than many observations in the middle years record (1900-1975)
486 of the record. The performance of the GMST and OHCA portions of EBM-KF model do vary
487 across half-centuries; the most noticeable biases are positive from 1900-1850 in GMST and
488 negative in OHCA from 1950-2000 (Fig. 4). These biases may be ameliorated by adjusting
489 various parameters away from literature values (perhaps adjusting γ away from $1.3 \text{ W/m}^2/\text{K}$
490 and allowing it to vary with time). Automated, optimized tuning of parameters is addressed in
491 Section 5c and is well-studied in Kalman filter applications (Zhang and Atia 2020); the
492 potential adoption of these tools to climate science is a key advantage of the EBM-KF
493 hybrid.

494

495 Fig. 4: EBM-KF state estimate for deep ocean OHCA in units of mean potential temperature
 496 from the same EBM-KF run as in Fig. 3. Annual-mean Zanna et al. (2019) reconstructions
 497 are assimilated (grey dots). Panels and colors as in Fig. 3.

498 Figure 4 shows the deep OHCA component of the EBM-KF and its associated
 499 uncertainties. While the OCHA data is autocorrelated more so than the annual GMST, the
 500 innovations for OHCA are again nearly Gaussian (panels 4b, 4c). In the context of this
 501 empirical probability distribution, each member of the Gaussian mixture has a larger σ given
 502 by the measurement uncertainties in the OHCA dataset relative to the predictive distribution.
 503 To average out to the nearly-Gaussian empirical probability distribution, it is unsurprising
 504 that nearly all autocorrelated OHCA measurements are also very close to the EBM-KF
 505 estimated state, rather than filling the full (light blue) predictive distribution as in Fig. 3.
 506 Reflecting this improvement in measurement accuracy (as incorporated via R_{var}), the ocean
 507 components of both $\sqrt{P_n}$ and $\sqrt{S_n}$ shrink dramatically over the 173 years. $2\sqrt{S_n}$, the predictive
 508 envelope for ocean potential temperature, drops from $\sim 0.070\text{K}$ by 1860 to 0.038K by 1985
 509 and then remains near this value. $2\sqrt{P_n}$, the climate state envelope width for OHCA, has a
 510 very slow initial convergence that reaches $\sim 0.014\text{K}$ by 1875 and then gradually falls to
 511 0.0095K by 2000.

512 *b. Using the EBM-KF to determine Policy Threshold Crossing*

513 A single GMST measurement is not an accurate measurement of anthropogenic
514 climate change due to the large internal variability of the system, and so a single annual
515 temperature above a particular policy threshold is not a guarantee of the climate state crossing
516 that threshold. One interpretation of “crossing” is when the uncertain climate state of GMST
517 (here estimated to match the “standard climate normal”, or 30-year mean GMST) is
518 determined with a given probability to have passed a policy threshold. This “climate state
519 above” the threshold definition was used by Tebaldi and Knutti (2018) for regional thresholds
520 and the IPCC AR6 (Lee, Marotzke et al.) who state “the time of GSAT exceedance is
521 determined as the first year at which 21-year running averages of GSAT exceed the given
522 policy threshold.” A second interpretation would be a high probability that next year’s
523 annual-mean GMST will exceed the policy threshold, or “annual temperature forecast above”
524 the threshold. The EBM-KF generates probability distributions for both the “climate state
525 above” and the “annual temperature forecast above” interpretations of whether a policy
526 threshold has been crossed. We use a 30-year averaging window nearly everywhere, but for
527 consistency with these practices we use a 21-year averaging window for raw ESM
528 simulations only in Fig. 10 and Supp. Fig 7.

529 This climate state above threshold, as in the IPCC definition, is given in the EBM-KF
530 by a Gaussian distribution (green in Fig. 5a) about the state \hat{T}_n with a variance given by P_n .
531 The IPCC has an ensemble of models to draw upon over both the historical period and future
532 projections, so the fraction of the 21-year means of each of the ensemble members found
533 above a given policy threshold determines the overall probability that the climate policy
534 threshold was crossed. This ensemble interpretation assumes the ensemble spread is a good
535 representation of GMST uncertainty – recent IPCC reports discount the 90% ensemble spread
536 to a 66% confidence range because coarse climate models under-represent internal variability
537 and model uncertainty as described in Box 4.1 (Collins, Knutti et al. 2013; Lee, Marotzke et
538 al.). The EBM-KF does not require a future projection to arrive at a present-day climate state,
539 because it already provides an instantaneous and continual estimate and draws from this *a*
540 *posteriori* state build the probability of threshold crossing. In other words, the probability of
541 the climate state exceeding the policy threshold is the cumulative distribution function (with
542 mean μ set to the policy threshold and variance $\sigma^2=P_n$ evaluated at \hat{T}_n . The EBM-KF climate
543 state covariance is chosen to reflect the uncertainty in the 30-year average of real-world

544 GMST (see Section 2c)—using 21 years to match the IPCC definition is a trivial
545 modification.

546 For the second interpretation of temperature forecast above the policy threshold, the
547 EBM-KF predicts a relevant window (blue in Fig. 5b) of possible next-year GMST
548 measurements. It is a Gaussian distribution centered at the projected state $\hat{T}_{n|n-1}$ with a
549 variance given by the innovation covariance (S_n): in other words, a simulated draw from the *a*
550 *priori* state. This uncertainty range reflects and encapsulates actual GMST measurements (see
551 Fig 3b). For an ensemble of ESMs, the analogous temperature forecast probability is the
552 fraction of ESMs at year n that are warmer than the policy threshold.

553 There is additional ambiguity regarding what "crossing a policy threshold" means
554 regarding any time-varying probability. Here we define (based on the 1σ confidence interval,
555 or the *likely* range in IPCC terminology) the "policy threshold crossing period" to span from
556 the earliest year when $\geq 15.9\%$ of climate states or temperature forecasts exceed the policy
557 threshold to the latest year when $\leq 84.1\%$ of climate states or temperature forecasts exceed
558 that policy threshold. A "policy threshold crossing instant" is the year when the probability of
559 exceeding the policy threshold is nearest to 50% while continuing to increase (or *as likely as*
560 *not* to have crossed the policy threshold in IPCC terminology). Regardless of whether an
561 ESM ensemble (see Supp. Fig. 7) or EBM-KF (see Fig. 5) is used, the temperature forecast
562 above threshold period has a longer duration than the climate state above period because the
563 uncertainty/ensemble spread in the annual forecasts is wider than the uncertainty/ensemble
564 spread of the time-averaged states. Both ESM ensemble and EBM-KF methods report similar
565 policy threshold crossing instants (Fig. 10). The Mt. Pinatubo eruption in 1991 resets the
566 $+0.5\text{K}$ threshold crossing repeatedly in both the EBM-KF and ESM ensemble, the rapid
567 energy balance perturbation due to elevated aerosols.

568

569 Fig. 5: a) EBM-KF and climate state crossing policy thresholds: As in Fig. 3, there are the
 570 EBM-KF GMST state estimate (navy blue line), confidence interval of the climate state (light
 571 green), and GMST measurements (gray dots). Additionally, policy thresholds (brown lines)
 572 are shown at 286.7K (+0K), 287.2K (+0.5K), and 287.7K (+1.0K) compared to the
 573 preindustrial baseline. Two inset boxes indicate threshold crossing probability, with a y-axis
 574 of cumulative probability (purple; from 0 to 1) and the x-axis in time (years). b) The
 575 projected GMST “weather” 95% confidence window is shown in light blue around the EBM-

576 KF GMST state estimate (navy blue line). Thus, the two inset boxes indicate the likelihood
577 that the actual GMST measurement will be above a particular policy threshold.
578

579 Fig. 5 quantifies the probability of crossing policy thresholds as a function of time
580 (purple), inset on top of the relevant GMST timeseries and spread. The EBM-KF climate
581 state estimate in Fig. 5a and annual temperature forecast in Fig. 5b are fairly aligned by year,
582 although these two quantities are in entirely different probability domains. As the EBM-KF
583 state estimate approaches any given policy threshold, the cumulative temperature policy
584 threshold approaches 0.5, or 50% at a "policy threshold crossing instant". The +0.5K policy
585 threshold had crossing instants in 1989, 1991, and 1996, while the +1.0K policy threshold's
586 crossing instant was in 2017. For the annual temperature forecast, the policy threshold
587 crossing periods were 1981-1998 for +0.5K, and 2013-present for +1.0K. The policy
588 threshold crossing periods for the climate state are briefer: 1988-1996 for +0.5K and 2016-
589 2018 for +1.0K (see Fig. 10). For comparison (Fig. 10) and another perspective (Supp. Fig.
590 7), the analogous climate state thresholds and temperature forecast thresholds are found for
591 LENS2.

592 *c. The spread from one member – using EBM-KF to generate an analog for an ESM large*
593 *ensemble spread*

594 There are many more past and future climate scenarios that researchers wish to
595 investigate than there are computational resources to run a full large ensemble for each
596 scenario. Fortunately, the EBM-KF allows for one or a handful of ESM simulations to
597 approximate the distribution of an entire ensemble spread (similar to an approach taken for
598 ensembles of ice sheet models in (Edwards, Nowicki et al. 2021)). The average "climate state
599 uncertainty" $\sqrt{P_n}$ following one model ensemble member ($\sim 0.038\text{K}$) nearly covers the spread
600 of "climate states" $(\hat{T}_n)_j$ within the entire hindcast LENS2 simulation ensemble (Fig 6a,e).
601 Considering any one simulation (run i) within LENS2, if we run the EBM-KF treating the
602 global average of simulated surface temperatures and deep ocean temperatures as
603 measurements $(\mathbf{y}_n)_j$, the resulting estimated state uncertainty timeseries $(\sqrt{P_n})_i$ has a specific
604 meaning regarding all other EBM-KF states $(\hat{T}_n)_j$, if this procedure is repeated for every run
605 (j). In particular, all simulated EBM-KF states $(\hat{T}_n)_j$ are distributed with a standard deviation
606 that is only 1.20 times larger on relative to a the average estimated state uncertainty $\overline{(\sqrt{P_n})_i}$,
607 and at worst 1.55 times larger than any particular $(\sqrt{P_n})_i$. So, the EBM-KF approximates what
608 "state uncertainty" intuitively means within the context of a large ensemble, a result
609 especially remarkable because the error terms (R and Q) were based on the HadCRUT5

610 dataset alone, not LENS2. Indeed, HadCRUT5 measurements themselves can also roughly
 611 approximate the LENS2 “state uncertainty” (see Fig. 6a,b,c). However, there are inter-annual
 612 differences which persist between runs of the ensemble and skew some climate states (\hat{T}_n);
 613 cooler and others warmer (Fig. 6d). Also, the current generation of ESMs tend to
 614 underestimate the full spread of climate variability appropriately. For instance, some weather
 615 models use stochastic noise to push their distribution wider than dynamic variation alone
 616 (Buizza, Milleer et al. 1999), and other numerical climate models perturb parameters to
 617 achieve the same distribution-widening effect (Duffy, Medeiros et al. 2023)16; Keil, 2021
 618 #215}.

619 Fig. 6: Comparison of the Kalman Filter States across the LENS2 ensemble. a) The EBM-KF
 620 *a posteriori* HadCRUT5 state estimate (thick blue) and its 95% confidence interval (light
 621 green), along with EBM-KF state estimates for each individual CESM2 ensemble member
 622 (orange lines) and their mean (thick black line). b) The differences between the “real”
 623

624 measurement based HadCRUT5 climate state and all LENS2 climate states, scaled by the
625 state standard deviation and plotted against the ideal normal distribution. c) In the quantile-
626 quantile plot, these differences between the “real” measurement based HadCRUT5 climate
627 state and all LENS2 climate states distributions agree. d) Climate states and associated
628 uncertainties arising from each of 89 LENS2 simulations and HadCRUT5 are compared to all
629 other LENS2 climate states, and the bias and standard deviation of the resulting empirical
630 distributions are plotted. e) An example of these empirical distributions is graphed, indicated
631 by the point circled in black within the scatterplot.
632

633 Fig. 6 shows that the EBM-KF climate state based on HadCRUT5 temperatures and
634 EBM-KF climate states based any one of the LENS2 ensemble members show the expected
635 level of consistency and Gaussian differences. The GMST was estimated from the GSAT of
636 each LENS2 ensemble member. Thus, the EBM-KF on observations or on any one of the
637 ensemble members does a good job of estimating the climate state (i.e., averaged over
638 internal variability) and its uncertainty as simulated by the LENS2.

639 *d. Sampling Future Projections from a Non-Gaussian Volcanic Distribution*

640 In standard climate assessments (e.g., IPCC 2021), future volcanism has long been singled
641 out as an unknown aspect of projected climate change in any given future year. The forcing
642 of historical-period climate models includes the effects of known past volcanoes, while the
643 forcing of future climate models includes only “background forcing from volcanoes”, i.e., an
644 expected average forcing value in future years. Because of the nonlinearities and feedbacks
645 in the climate system, applying an average forcing is not the same as averaging over
646 individual events—neither is the effect of individual volcanoes on policy thresholds (as seen
647 from Pinatubo in Fig. 5). However, running an ESM ensemble of sufficient size to explore
648 the low probability of a large volcanic eruption in any potential year is not computationally
649 feasible using traditional ESMs—it is easily accomplished with the EBM-KF.

650

651 Fig. 7: Future GMST projections of SSP1-2.6 (a) and SSP3-7.0 (b) scenarios using sampled
 652 measures of volcanic activity and greenhouse gas concentrations calculated according to
 653 MAGICC7.0 (Meinshausen, Nicholls et al. 2020). The historical Mt. Pinatubo eruption in
 654 1991 is shown in the lower left corner of both graphs for scale. 10 of the sampled 10000
 655 potential future climate states are graphed (thin blue). There is a gap from 2022 to 2023
 656 between the past EKF state estimates and future projections, to emphasize the distinction
 657 between these even though the same state estimate and state covariance is carried forward in
 658 time for each future sample. The probability density function formed by taking the
 659 summation of all sampled Gaussian kernels at each time point is shaded in green on a
 660 logarithmic scale. Pink lines show the 2.5-97.5% confidence interval of these asymmetrical
 661 probability density functions.

Projected Ocean Heat Content State

662

663 Fig. 8: Future OHCA projections of SSP1-2.6 (a) and SSP3-7.0 (b) scenarios using sampled
 664 measures of volcanic activity and greenhouse gas concentrations calculated according to
 665 MAGICC7.0 (Meinshausen, Nicholls et al. 2020). 10 of the sampled 10000 potential future
 666 climate states are graphed (thin blue). There is a gap from 2023 to 2024 between the past
 667 EKF state estimates and future projections, to emphasize the distinction between these even
 668 though the same state estimate and state covariance is carried forward in time for each future
 669 sample. The probability density function formed by taking the summation of all sampled
 670 Gaussian kernels at each time point is shaded in green on a logarithmic scale. Pink lines show
 671 the 2.5-97.5% confidence interval of these asymmetrical probability density functions.

672

673 Fig. 7 shows the future projections of GMST using EBM-KF, including sampling
 674 from future volcanoes for two scenarios, and the corresponding projections of OHCA are in
 675 Fig. 8. Note that without the sampled distribution of these volcanic eruptions, the probability
 676 distributions would be symmetric and closely resemble those in Supp. Fig. 8, but all state
 677 trajectories would follow the mean (darkest green band). SSP1-2.6 in Fig 7a is has CO₂
 678 emissions that sharply decline after 2020 to keep GMST rise below 2K (van Vuuren, den
 679 Elzen et al. 2007; van Vuuren, Stehfest et al. 2017). SSP3-7.0 in Fig 7b is a higher emission
 680 scenario in which CO₂ emissions double by 2100 (Fujimori, Hasegawa et al. 2017). Note that
 681 this probability density is not symmetrical - there is a much more gradual tapering off on the
 682 cooler side because of volcanic eruptions. Indeed, the volcanic eruptions dominate the future

683 uncertainty over the slowly growing state uncertainty and rival or exceed the scenario
684 uncertainty up until about 2060. By contrast, the LENS2 using “background” future
685 volcanism has a symmetrical distribution for future projections of the same SSPs (Supp Fig.
686 8).

687 Regarding future policy threshold crossings, the uncertainty regarding volcanic
688 eruptions lessens the difference between the climate state threshold crossing interval and the
689 temperature prediction threshold crossing interval.

690

691 **4. Discussion**

692 The EBM-KF climate state estimate resembles other standard estimates of climate state, but it
693 has advantages they do not share. The EBM-KF algorithm, because of its relationship to a
694 forward or “blind” EBM, can be projected forward in time without temperature observations
695 and thus can be used in many situations. Unlike an ESM, the EBM-KF benefits from data
696 assimilation due to its Kalman filter nature and thus remains close to observations or other
697 synthetic data (e.g., the ensemble of potential volcanic activity futures in Section 4d). Unlike
698 an ensemble Kalman filter approach that can reweight a full-physics ESM ensemble toward
699 observations, the EBM-KF has negligible computational cost and can thus examine rare,
700 long-tailed events such as volcanoes with the necessary number of samples (Section
701 4d). Additionally, tuning of the EBM parameters and uncertainty quantification of these
702 results can benefit from the literature and algorithms to optimize Kalman filter parameters.

703 *a. Comparison to Previous Estimation Methods of the Climate State*

704 In a direct comparison (Fig. 9) of the state estimated from the EBM-KF (Fig. 3) and
705 that estimated by the 30-year running mean (Fig. 1) and the LENS2 ensemble (Supp. Fig. 8),
706 the EBM-KF has slightly more year-to-year variation than the 30-year mean and less than
707 LENS2. Departures from the main Gaussian cloud in all methods represent volcanoes. The 5
708 largest eruptions which caused the largest dip in EBM-KF state are labeled in Fig. 9,
709 corresponding to the 5 peaks in $AOD \geq 0.06$ plotted in Figure B1 in the appendix. The
710 climate effects of these major tropical volcanic eruptions have been studied extensively
711 (McCormick, Thomason et al. 1995; Jones and Kelly 1996). Note for the eruptions listed,
712 plus many others, the dips in the EBM-KF mean state correspond with dips in the sample
713 mean of the LENS2 simulations. However, the earliest AOD values provided by Sato (1993)

714 also demonstrate a major spike at 1856, which is not reflected in the LENS2 simulations.
 715 This may correspond to either the 1956 eruptions of Komaga-take, Japan or Mt. Awu,
 716 Indonesia, and we labeled this with the latter eruption because tropical volcanic eruptions
 717 typically have a much larger climate impact (Marshall et al. 2022).

718

719 Fig. 9 a: Direct GMST “climate state” comparison of the 30-year averaged GMST (green),
 720 the EBM-KF state (navy blue), and the ensemble mean of GSAT in the LENS2 simulations
 721 (blue). b) For both the 30-year averaged GMST (green) and the EBM-KF state (blue), the
 722 distribution of innovations is plotted against the distribution of differences between the state
 723 estimate and instantaneous GMST measurements. Major volcanic eruptions are labeled with
 724 light grey symbols in b), and the corresponding eruption times are drawn in dotted vertical
 725 light grey lines in a). Change 3 years after all eruptions are marked in b), except Mt. Pinatubo
 726 which was marked for 8 years to demonstrate the rapid warming rebound in the EBM-KF
 727 state.

728

It is beyond the scope of this paper to detail the characteristics of the large and
 729 growing variety of “mean state” definitions, but a summary is useful. For all methods we
 730 have examined (30-year mean – Fig. 1, EBM-KF – Fig. 3, LENS2 model ensemble mean –
 731 Supp. Fig. 8, purely statistical methods - Supp. Figs. 2c, 2d, 3), the differences in the
 732 estimated climate state are relatively small in available years (on the order of 0.1K – see
 733 Supp. Fig. 9, column 1). The largest differences seen between these methods lie in the spread
 734 of the changes from year to year (see Supp. Fig. 9, column 2) and persistent mean anomalies
 735 relative to observations, particularly so in the forward, blind LENS2 ensemble (see Supp. Fig.
 736 9, column 4).

737

The primary distinction of our EBM-KF method and all existing alternative
 738 definitions is the integrated quantification of uncertainty. While many methods exhibit a
 739 relationship between the “mean state” and “sample” that varies in time, the EBM-KF (and the

740 related RTS) quickly converge to a stable state uncertainty of 0.03K (see Supp. Fig. 10). Our
741 choice of method was motivated by the mathematical compatibility between the governing
742 equation for a Kalman filter and that of an EBM, which is not true of many alternatives,
743 e.g., a Butterworth filter or changepoint analysis and an EBM.

744 *b. Comparison to a Large Ensemble of an Earth System Model – CESM2*

745 The chief advantage of EBM-KF over an ensemble of ESMs is that it replicates most
746 statistical features while being trivial to compute. Fig. 6 suggested that any of the ensemble
747 members or the observed temperature record could be used together with EBM-KF to
748 recreate the climate state, but now we examine if we can anticipate or improve on the
749 ensemble statistics *without the ensemble*.

750 First, we examine the basic statistical character of LENS2. The distribution of annual
751 differences of all ESM trajectories from the ensemble mean are remarkably close to Gaussian
752 (see Supp. Fig. 5). Therefore, again due to the central limit theorem, this fundamental
753 assumption of the EBM-KF is also met by GSAT in the CESM2. The standard deviation does
754 insignificantly rise with time in LENS2 over the entire simulation duration ($p=0.17$). Before
755 2065 this rise is significant ($p=1.2 \cdot 10^{-6}$, again see Supp. Fig. 5) while relatively small (linear
756 trend $R^2=0.105$ and only 8.9% rise in σ from 1850-2065). The time-averaged standard
757 deviation of 0.127K was close to both the chosen value of the GMST measurement noise $\sqrt{R_n}$
758 $\in [0.102\text{K} - 0.146\text{K}]$ (see section 2c) and the converged values in the EBM-KF of the GMST
759 innovation covariance $\sqrt{S_n} \approx 0.13\text{K}$ in 1860, later $\sqrt{S_n} \approx 0.11\text{K}$ since 1975. Examining
760 skewness and kurtosis, the distribution of simulations about the mean LENS2 GSAT state is
761 not meaningfully altered as the climate warms (see Fig. 9).

762
763
764 Next, we evaluated how well this LENS2 captures the overall shape of the observed
765 HadCRUT5 temperatures, given that it is not constrained directly by these observations. The
766 absolute temperature of the LENS2 runs had to be revised down by a full 1.75K to match the
767 1960-1990 30-year climate normal (Jones and Harpham 2013). Other authors have also noted
768 this high absolute temperature as well as the high climate sensitivity of CESM2 (Gettelman,
769 Hannay et al. 2019; Feng, Otto-Bliesner et al. 2020; Zhu, Otto-Bliesner et al. 2022).

770
771 We also compared EBM-KF projections with LENS2 projections. Both Fig 7b and the
772 right-hand portion of Fig 9 trace out roughly the same shapes, as both are forced by the SSP3-
773 7.0 projections. The largely symmetric variation in the large ensemble is driven by dynamical

774 instability. This is fundamentally different from the EBM-KF, which samples a noisy
775 distribution of volcanic eruptions, yielding asymmetrical variation. LENS2 projections based
776 on SSP3-7.0 achieve a slightly higher mean temperature in 2100 (291.3K, +4.6K warming)
777 than the equivalent EBM-KF projection (290.9K, +4.2K warming), despite the LENS2
778 simulations being cooler throughout most of the 20th century and early 21st century (see Fig
779 8a). This reflects the high climate sensitivity of CESM2. Across all CMIP6 models (Lee,
780 Marotzke et al. 2021; Tebaldi, Debeire et al. 2021) the projected warming is under this
781 scenario is 3.9K with 5-95% range (+2.8K, +5.5K), closer to the EBM-KF projection.

782 Regarding the various types of climate policy thresholds, the LENS2 can be used to
783 generate very similar results to the EBM-KF (Supp. Fig. 7, Fig. 10). Differences in absolute
784 probability and policy threshold crossing instants reflect differences in the modeled climate
785 states: particularly that the LENS2 ensemble was slightly cooler than the EBM-KF model
786 after correcting to the same preindustrial temperature, so policy thresholds were crossed 3-5
787 years later (Fig. 10). The eruption of Mt. Pinatubo caused the policy threshold of +0.5K to be
788 crossed in three instants within the EBM-KF model, because this eruption temporarily cooled
789 the climate state back below the threshold temperature. The first of these EBM-KF crossings
790 coincides very closely with the (single) policy threshold crossing instant of the 30-year
791 running mean (indicated by orange asterisks). The 21-year running averages of the LENS2
792 simulations only crossed the 0.5K threshold once, illustrating how the EBM-KF state
793 estimate fundamentally differs from a running mean.

794
 795 Fig. 10: Comparison of historical policy threshold crossing probabilities for the EBM-KF
 796 (purple, reproduced from Fig. 4 insets) and CESM2 LENS simulations (pink). The climate
 797 states above a) +1.0K and c) +0.5K policy thresholds compare EBM-KF with 21-year
 798 averages of the CESM2 simulations. The annual temperature forecasts above b) +1.0K and c)
 799 +0.5K are also compared. Policy threshold crossing instants (intersecting horizontal and
 800 vertical lines) and crossing windows (arrows at bottom) are also shown. An orange asterisk
 801 indicates 1987 in c) and d), the year that 30-year running mean of HadCRUT5 GMST crossed
 802 the +0.5K policy threshold, the +1.0K crossing instant of the 30-year running mean cannot be
 803 determined for the upper panels as it is within 15 years of the present.

804 *c. Potential Issues with the EBM-KF and Future Extensions*

805 This first climate Kalman filter does not generate regional temperatures nor other
 806 essential climate variables, such as precipitation. These variables are often highly non-
 807 Gaussian, and may require an understanding of regional “tipping points” or other important
 808 nonlinear process aspects of climate change. Therefore, this first EBM-KF is far from

809 generating the information required to replace many aspects of large ensembles. An expanded
810 global climate state vector, including precipitation, seasonal temperature, or eigenvalues of
811 spatially decomposed principal components (e.g., El Nino / Southern Oscillation) might be
812 appended into this statistical framework with appropriate physical forward modeling (Yang,
813 Li et al. 2018).

814 Astute readers may note the estimated climate state and covariance within the EBM-
815 KF is influenced by the particular choice of reconstructed HadCRUT 5 GMST and Zanna et
816 al. (2019) OHCA. With only minor modifications, the EBM-KF method could be used with
817 multiple annual reconstructions at the same time, e.g., GISTEMP GMST (Lenssen, Schmidt
818 et al. 2019) or other OHCA reconstructions (Cheng, Trenberth et al. 2017; Ishii, Fukuda et al.
819 2017), considering each as only an estimate of the true GMST or OHCA (Willner, Chang et
820 al. 1977). Reconstructions of sea level rise could be used from different sources as
821 measurements of OHCA (Fox-Kemper, Hewitt et al. 2021).

822 Here we use pre-selected, constant parameters at their published values in the EBM-
823 KF. However, methods for tuning parameters, including time-dependent parameters, within
824 Kalman filters are much more extensively studied mathematically (Chen, Heckman et al.
825 2018 ; Zhang and Atia 2020 ; Chen, Heckman et al. 2021) than the methods thus far applied
826 in climate sciences to diagnose parameter variations within energy balance models (e.g., the
827 regional effects diagnosed from CCSM4 in (Armour, Bitz et al. 2013; Gregory and Andrews
828 2016)). Our EBM-KF hybrid presents an opportunity to adopt KF parameter optimization
829 methods for the GMST, OHCA projection optimization problem. In a preliminary experiment
830 with Bayesian parameter search to give better estimates of the coefficients in the blind EBM,
831 the prior distributions of these coefficients (rather than point estimates) were extracted from
832 climate science literature, followed by a Metropolis-Hastings search. Several parameters
833 required further care or tuning to achieve desired constraints (e.g., balanced energy transfer
834 in the preindustrial climate), such as the main coefficient multiplying all longwave radiation
835 terms and the temperature exponent. However, identifiability and overfitting are challenges
836 of this approach and deserve more attention than the scope of this paper allows. In this first
837 illustration of the system, opportune imperfections in the point estimates given by literature
838 sources allow demonstration of the course-corrective properties of the EBM-KF (Fig. 4).

839 *d. Policy Utility*

840 Real-time, accurate knowledge of policy threshold crossing will allow for more
841 prudent planning and more comprehensible communication of climate science to the public.

842 For instance, while the “Climate Clock” (<https://climateclock.world>) intends to communicate
843 the urgency of the climate crisis with a countdown to the estimated expenditure of our
844 remaining carbon budget, only a static date informs it. In contrast, an EBM-KF threshold
845 countdown would reflect the most recently measured state of the Earth system and up-to-date
846 emissions and present limits on future emissions. Climate modeling with ESMs is slow,
847 computationally expensive, and typically performed with blind models that do not respond to
848 the latest observations. The relatively simple question, “How did the COVID-19 lockdowns
849 and the 8% reduction in CO₂ emissions impact the near-term climate?” required hundreds of
850 ESM simulations to yield a statistically insignificant answer (Jones, Hickman et al. 2021).
851 That sort of modeling effort, arriving months or years after the question was posed, is an
852 unsatisfactory prize for many aspects of communication and decision making for the annual
853 profit or election term. The EBM-KF can produce the result that an 8% emissions reduction
854 over 2 years cools the climate state by ~0.0017K and pushes back the threshold crossing time
855 by 1.2 months – an insufficient reduction in climate change, but at least precisely and rapidly
856 quantified. The EBM-KF is sufficiently fast that, once fully calibrated, it could be easily
857 embedded as a interactive web tool for such exploration.

858 Additionally, Kalman filters are often used for process control (Myers and Luecke
859 1991; Lee and Ricker 1994), and in this case an EBM-KF could be used to optimize climate
860 change mitigation strategies (Filar, Gaertner et al. 1996; MacMartin, Kravitz et al. 2014;
861 Kravitz, MacMartin et al. 2016). Once a space of potential climate solutions has been
862 defined, the EBM-KF can work seamlessly with a variety of optimizers to find the maximum
863 climate benefit at the lowest societal cost.

864 **6. Conclusion**

865 The EBM-KF presented in this paper represents somewhat of a compromise between
866 a 30-year running average of GMST (the historical definition of climate) and state-of-the-art
867 ESM large ensembles such as CESM2 LENS. The variance of the EBM-KF GMST climate
868 state, which also tracks the ocean heat content anomaly (OHCA) in the form of deep ocean
869 potential temperature, is constructed to be very close to that of a running 30-year mean. This
870 filtered climate state does an excellent job in describing the overall shape of the measured
871 GMST and OHCA values ($R^2 = 0.90$ and 0.92). However, this EBM-KF climate state
872 estimate has no lag in reporting after annual observations are collected. In comparison to the
873 ensemble spread of a hindcast ensemble of an ESM (LENS2), which is presently the typical
874 brute-force method for quantifying internal variability and probabilistic futures, the EBM-KF

875 provides a similar Gaussian distribution. In future projections of climate under SSP
876 trajectories, the efficiency of the EBM-KF allows for sampling non-Gaussian, intermittent
877 distributions: an exponential mixture model of future volcanic eruptions causes the EBM-KF
878 GMST climate states to be negatively skewed, unlike LENS2 which remains Gaussian. This
879 allows for the first time precise quantification of volcanism on policy threshold crossings.
880 The EBM-KF approach has transparent, clean physical parameters of the EBM that can be
881 directly measured or taken from estimates in modeling literature, leading to trivial uncertainty
882 quantification by the Kalman filter machinery under fixed parameters. We investigated if the
883 EBM-KF needs time-varying EBM parameters or other extensions, although a thorough
884 treatment is left for future work. While the EBM-KF does not predict all climate variables of
885 interest, it is a powerful, transparent, and inexpensive tool that may be readily combined with
886 other approaches.

APPENDICES

906

Appendix A: Derivation of the Blind Energy-Balance Model

907 A1: Overall Structure of the Model

Symbols of Energy Balance Model

908

909 Fig. A1: Diagram listing the symbols in the energy balance model and its basic structure.

910 In the schematic diagram above, one stream of incoming solar shortwave energy G_0^* is
 911 successively fractionated by three reflective layers until a portion warms the ground and
 912 surface ocean. Then this surface layer radiates longwave infrared energy back to space j^* ,
 913 again with greenhouse “reflection” in two layers. The surface ocean warms the deep ocean
 914 with set thermal insulation between them.

915 Temperature-dependent feedbacks are shown as cyclical arrows, with positive and
 916 negative feedback indicated relative to the overall energy balance. Positive feedbacks
 917 increase the energy flowing to the surface at higher surface temperatures T_n either by
 918 decreasing the fraction of shortwave reflection or increasing the greenhouse “reflection”.
 919 Prescribed forcings are indicated by gear symbols. Unknown coefficients $\beta_0 \beta_1 \beta_2 \beta_3$ exist
 920 respectively within the terms: $\tilde{g}_n, f_{H2O}, f_{\alpha A}, f_{\alpha S}$. All these symbols are defined below.

921 Reiterating the overall structure in the model with equations, T_n is the temperature of the
 922 surface in calendar year n (e.g. 2000), θ_n is the potential (or conservative) temperature of the
 923 deep ocean in that same year, and H_n is the total ocean heat content combining the heat in the

924 surface ocean and deep ocean. The calendar year (or index since 1850) is represented by n ,
 925 and k is 1 year, the time step of this iterative model. Units are omitted in this section for
 926 clarity.

$$927 \quad \Delta \text{Energy_total} = \phi_{\text{SW}}(\text{in}) - \phi_{\text{LW}}(\text{out}) \quad (\text{A1})$$

$$928 \quad \Delta \text{Energy_surf} = \phi_{\text{SW}}(\text{in}) - \phi_{\text{LW}}(\text{out}) - Q_{\text{surf_deep}} \quad (\text{A2})$$

$$929 \quad \frac{T_{n+1}-T_n}{k} C_{\text{surf}} = G_0^* * \tilde{d}_n * f_{\alpha A}(T_n) * f_{\alpha S}(T_n) - j^*(T_n) * \tilde{g}_n * f_{H2O}(T_n) - \gamma * (T_n - \theta_n - \zeta) \quad (\text{A3})$$

$$930 \quad \frac{\theta_{n+1}-\theta_n}{k} C_{\text{deep}} = \gamma * (T_n - \theta_n - \zeta) \quad (\text{A4})$$

$$931 \quad H_n = (T_n - T_{1850}) * C_{\text{surf0}} + (\theta_n - \theta_{1850}) * C_{\text{deep}} \quad (\text{A5})$$

$$932 \quad \theta_n = (H_n - (T_n - T_{1850}) * C_{\text{surf0}}) / C_{\text{deep}} + \theta_{1850} \quad (\text{A6})$$

$$933 \quad H_{n+1} = (T_{n+1} - T_{1850}) * C_{\text{surf0}} + \gamma * (T_n - \theta_n - \zeta) + (\theta_n - \theta_{1850}) * C_{\text{deep}} \quad (\text{A7})$$

$$934 \quad H_{n+1} - H_n = (T_{n+1} - T_n) * C_{\text{surf0}} + \gamma * (T_n - \theta_n - \zeta) \quad (\text{A8})$$

$$935 \quad \text{Derivatives of } \theta_n: \quad \frac{\partial \theta_n}{\partial H_n} = 1/C_{\text{deep}} \quad (\text{A9a}) \quad \frac{\partial \theta_n}{\partial T_n} = C_{\text{surf0}}/C_{\text{deep}} \quad (\text{A9b})$$

936 On the right side of equation A3, both the shortwave radiative flux $\phi_{\text{SW}}(\text{in})$ and longwave
 937 radiative flux $\phi_{\text{LW}}(\text{out})$ take the same form: (source $\{G_0^*, j^*(T_n)\}$) * (prescribed attenuation
 938 $\{\tilde{d}_n, \tilde{g}_n\}$) * (attenuations with feedback $\{f_{\alpha A}(T_n) * f_{\alpha S}(T_n), f_{H2O}(T_n)\}$). C_{surf} , the heat capacity
 939 of the surface (including the atmosphere, thermally active soil, and an 86m upper layer of the
 940 ocean), was known least precisely of all coefficients: $17 \pm 7 \text{ W (year) m}^{-2} \text{ K}^{-1}$, (Schwartz
 941 2007). The deep ocean layer (technically the zone where most of the ocean warming occurs)
 942 was chosen for the purpose of heat capacity estimation to be an additional 1141m within the
 943 71% of area covered by ocean based on previous work of this heat transfer process.
 944 (Geoffroy, Saint-Martin et al. 2013; Hall and Fox-Kemper 2023) This gives $C_{\text{deep}} = 1141\text{m}$
 945 $* 0.71 * 1030\text{kg/m}^3 * 4180\text{Ws/kg/K} * 1 \text{ yr} / (3.154 * 10^7\text{s}) = 155.7 \text{ W (year) m}^{-2} \text{ K}^{-1}$. Constants
 946 γ, ζ form a linear heat flux $Q_{\text{surf_deep}}$ into the deep ocean, as discussed below. Radiative
 947 fluxes are signified in this text by the symbol ϕ , followed by specific details of that flux.

948 **A2: Individual Functional Parts and Derivation**

949 G_0^* is the extraterrestrial radiance, taken for the purposes of this model derivation to be (solar
 950 radiance)/4 = $1360 \text{ W/m}^2 / 4 = 340 \text{ W/m}^2$. Estimates of actual annual extraterrestrial radiance

951 (total solar irradiance) indicate that it has varied since 1850 between 340.06 W/m² and 340.49
 952 W/m² according to the Naval Research Laboratory 2 solar irradiance model
 953 ([NRLTSI2_v02r01](#) (Coddington, Lean et al. 2017)). Within the hindcast EBM-KF model
 954 these NRL2 estimates were used, but this had a negligible effect on the model results
 955 compared to a constant 340 W/m² value.

956 \tilde{d}_n is the prescribed shortwave radiation attenuation due to volcanic dust, the direct radiative
 957 effect of anthropogenic aerosols, and non-cloud atmospheric effects. This stochastically
 958 varying quantity can be calculated from the (unitless) stratospheric optical depth AOD_n (Sato,
 959 Hansen et al. 1993; Vernier, Thomason et al. 2011), according to the formula given by
 960 Harshvardan and King (1993; Schwartz, Harshvardhan et al. 2002). ($g=0.853$ is the middle of
 961 the given range). The AOD_n values used are forcings for the GISS climate model from 1850
 962 – 1978 (https://data.giss.nasa.gov/modelforce/strataer/tau.line_2012.12.txt, AOD_n at 550nm)
 963 and globally averaged measurements from the GloSSAC_V2 satellite measurement product
 964 (Nasa/Larc/Sd/Asdc 2018) from 1979 – 2021
 965 (https://asdc.larc.nasa.gov/project/GloSSAC/GloSSAC_2.0, AOD_n at 525nm). These
 966 wavelengths are at the shorter end of the 0.25-4 μm range of incoming solar shortwave
 967 energy ϕ_{SW} , allowing satellites to detect dust reflectance.

$$968 \quad \tilde{d}_n = \frac{1.33}{AOD_n * (1-g) + 1.43}, \quad g \in [0.834, 0.872] \quad (A10)$$

$$969 \quad \tilde{d}_n \approx \frac{9.07}{AOD_n + 9.73} \quad (A11)$$

970 Utilizing the equation above to calculate the dry-atmosphere reflected energy during a
 971 relatively aerosol-free period (2000-2005), when the aerosol optical depth was about 0.002m:

$$972 \quad \phi_{SW_{clearsky}}^{refl\ by\ dryatm} = G_0^* * (1 - \widetilde{d}_{2002}) = 340 \frac{W}{m^2} (1 - \frac{9.07}{0.002+9.73}) = 23.1 \frac{W}{m^2} \quad (A12)$$

973 This value agrees with the clear-sky reflected energy (53 [52-55] W/m²) minus reflected
 974 surface energy (33 [31-34] W/m²), of 20 [18-24] W/m² reported by Wild, Hakuba et. al.
 975 (2019). Furthermore, the measured and inferred aerosol optical depth measurements already
 976 include those contributions from the anthropogenic sources.

977 $f_{\alpha A}(T_n)$ is the additional atmospheric shortwave attenuation due to cloud albedo, while $f_{\alpha S}(T_n)$
 978 is the surface shortwave attenuation due to ground albedo. A portion of this varying cloud
 979 albedo is direct thermal feedback, whereas another portion is due to cloud seeding by

980 anthropogenic aerosols. To contain the EBM model's complexity, the changing ground
 981 albedo is assumed to be only thermal feedback: the shortwave aspect of land use changes are
 982 neglected. Taken together, these two terms and \tilde{d}_n yield an overall absorption of 0.707 as
 983 measured from March 2000 to February 2005 by the CERES satellite (Wielicki, Barkstrom et
 984 al. 1996; Loeb, Wielicki et al. 2009), or equivalently a top-of-atmosphere, all-sky albedo of
 985 0.293. Decomposition of this overall albedo into its clear-sky component (0.153) yields a
 986 ground * dry atmosphere absorption fraction of 0.847.

$$987 \quad 0.847 = \overline{d}_{2002} * f_{aS}(T_{2002}) = 0.932 * f_{aS}(T_{2002}), \quad \text{thus} \quad f_{aS}(T_{2002})=0.909 \quad (\text{A13})$$

$$988 \quad 0.707 = \overline{d}_{2002} * f_{aA}(T_{2002}) * f_{aS}(T_{2002}) = 0.847 * f_{aA}(T_{2002}), \quad f_{aA}(T_{2002})=0.834 \quad (\text{A14})$$

989 Verifying the reflected energies:

$$990 \quad \phi_{\text{SW clearsky}}^{\text{refl by gnd}} = G_0^* * \overline{d}_{2002} * (1 - f_{aS}(T_{2002})) = 340 \frac{W}{m^2} * 0.932 * 0.091 = 28.8 \frac{W}{m^2} \quad (\text{A15})$$

$$991 \quad \phi_{\text{SW allsky}}^{\text{refl by gnd}} = G_0^* * \overline{d}_{2002} * f_{aA}(T_{2002}) * (1 - f_{aS}(T_{2002})) = 24.1 \frac{W}{m^2} \quad (\text{A16})$$

$$992 \quad \phi_{\text{SW allsky}}^{\text{refl by clouds}} = G_0^* * \overline{d}_{2002} * (1 - f_{aA}(T_{2002})) = 52.6 \frac{W}{m^2} \quad (\text{A17})$$

993

994 There is a slight discrepancy in the clear-sky ground-reflected energy relative to the literature
 995 value (33 [31-34] W/m²), but the all-sky reflected energies are much more closely aligned:
 996 the ground reported value is 25 [23-26] W/m², and the dry atmosphere + cloud reported value
 997 is 75 [71, 77] W/m², compared to this inferred value of 52.6 + 24.1 = 76.7 W/m². (Wild,
 998 Folini et al. 2015) Note that this shortwave flux equation does not consider shortwave energy
 999 absorbed into the atmosphere, a substantial simplification.

1000 $j^*(T_n) = \sigma_{\text{sf}} T_n^4$ is the ideal black body radiation or Planck feedback, which derives from
 1001 quantum mechanics, particularly the Stefan-Boltzmann law (Boltzmann 1884), which gives
 1002 the Stefan-Boltzmann constant $\sigma_{\text{sf}} = 5.670 \cdot 10^{-8} \text{Wm}^2\text{K}^{-4}$ as a coefficient. For the Earth, because
 1003 the temperature is in the neighborhood of 287K, this black body radiation is primarily in the
 1004 infrared spectrum, between 200 and 1200 cm⁻¹ (Zhong and Haigh 2013).

1005 \tilde{g}_n is the prescribed longwave attenuation due to CO₂ and other anthropogenic greenhouse
 1006 gases (CH₄, NO₂, O₃, halogens), which is half of the fraction of radiative energy absorbed by
 1007 those gases (because half is re-emitted upwards and half downwards). This absorbed,

1008 downwards-emitted fraction increases linearly by a factor of β_0 with respect to the logarithm
 1009 of the CO₂ concentration measured in ppm (see Figure 6b of (Zhong and Haigh 2013)). CO₂
 1010 concentrations were taken as the historical concentrations used in the NASA GISS climate
 1011 model 1850-1979 (<https://data.giss.nasa.gov/modelforce/ghgases/Fig1A.ext.txt>) and the
 1012 NOAA global averages from 1980-2021
 1013 (https://gml.noaa.gov/webdata/ccgg/trends/co2/co2_annmean_gl.txt).

$$1014 \quad \phi_{LW}(\text{out}) = j^*(T_n) - \frac{\phi_{LW}(\text{absorbed})}{2} = j^*(T_n) * \tilde{g}_n * f_{H_2O}(T_n) \quad (\text{A18})$$

$$1015 \quad \tilde{g}_n * f_{H_2O}(T_n) = \left(1 - \frac{\phi_{LW}(\text{CO}_2 \text{ absorb})}{2j^*(T_n)}\right) * \left(1 - \frac{\phi_{LW}(\text{H}_2\text{O absorb})}{2j^*(T_n)}\right) \approx \left(1 - \frac{\phi_{LW}(\text{CO}_2 \text{ absorb}) + \phi_{LW}(\text{H}_2\text{O absorb})}{2j^*(T_n)}\right) \quad (\text{A19})$$

$$1016 \quad \tilde{g}_n = 1 - \beta_0 \log_{10}([\text{CO}_2]_n) < \mathbf{1} \quad (\text{A20})$$

1017 Equation A18 refers to a single-layer atmosphere assumed by prior researchers such as
 1018 Kravitz, Rasch, et. al. (2018) While the technically correct separation of A18 is shown on the
 1019 right hand side of A12, the form for the product of $\tilde{g}_n * f_{H_2O}(T_n)$ was chosen specifically to
 1020 resemble the previous shortwave energy expressions, essentially representing CO₂ in an
 1021 atmospheric layer above H₂O (sequential filtering). Relating these two representations
 1022 demands the simplification that both the longwave radiative fluxes absorbed by CO₂ and H₂O
 1023 are each smaller than twice the total ground-emitted longwave radiative flux, so their product
 1024 is yet smaller and can be neglected. Indeed, for CO₂ this ratio $\frac{\phi_{LW}(\text{CO}_2 \text{ absorb})}{2j^*(T_n)} =$
 1025 $\beta_0 \log_{10}([\text{CO}_2]_n)$ is in the range [0.165, 0.176] and for H₂O the analogous ratio is in the range
 1026 [0.250, 0.259] so their product (the difference between the RHS and LHS of A12) is at most
 1027 0.045. This difference in energy flux would be large enough to cause significant inaccuracies
 1028 in the energy balance model (larger than the anthropogenic global warming signal), should
 1029 parameters from a single-layer atmosphere be used in a sequential filter model. Thus, the
 1030 critical parameters β_0 and β_1 must be calculated within the framework of the chosen model
 1031 (here a sequential filter – see below), after which this distinction only matters to the higher-
 1032 order terms of the deviations from the preindustrial energy flux $(0.176-0.165) * (0.259-0.250)$
 1033 ≈ 0.0001 , a negligible fraction.

1034 More complex functions for \tilde{g}_n exist involving functions for each individual
 1035 greenhouse gas (Meinshausen, Nicholls et al. 2020) but for the purposes of simplifying this
 1036 energy balance model, only one “effective greenhouse” concentration is used. Our “effective

1037 greenhouse gas concentration” includes CH₄, N₂O, O₃, contrails, stratospheric water vapor,
 1038 land use, and black carbon on snow but excluding anthropogenic atmospheric aerosols
 1039 (Forster, Smith et al. 2023). Formally, land use and black carbon on snow should be included
 1040 as a prescribed change to the $f_{\alpha S}$ function on the shortwave side but in combination these two
 1041 amount to within -0.15 W/m², less in absolute value than all the other aforementioned
 1042 “combined greenhouse forcing” components aside from contrails and stratospheric water
 1043 vapor. Similarly, the prescribed contribution of stratospheric water vapor should formally be
 1044 within the $f_{H_2O}(T_n)$ function not lumped with the other greenhouse gases, but as this
 1045 represents only 0.05 W/m² at most, this is inconsequential (variations in incoming solar
 1046 insolation are of a similar magnitude). We determined the “effective CO₂ concentration” by
 1047 first fitting a function relating CO₂ concentrations reported above to the CO₂ forcings
 1048 reported by Forster (2023).

$$1049 \quad \phi_{LW}^{CO_2} = 12.74 \log_{10}([eCO_2]) - 31.5 \quad (A21)$$

1050 Then by summing all “effective greenhouse gas” reported energy fluxes, the above function
 1051 was inverted to determine the “effective CO₂ concentration.” These ranged from 278 ppm (or
 1052 $\log_{10}([eCO_2]) = 2.444$ when there was no “effective greenhouse gas” energy flux to
 1053 558.7ppm or $\log_{10}([eCO_2]) = 2.747$ in 2022.

1054 $f_{H_2O}(T_n)$ is the additional atmospheric longwave attenuation due to water vapor and other
 1055 gasses, including both lapse rate and relative humidity. The precise functional form of this
 1056 feedback function is unknown, as is the functional form of the two shortwave feedbacks,
 1057 partially due to disagreements between paleoclimate inferences and ESMs. We thus
 1058 introduced the following 3 functions, which incorporate an additional 3 positive β
 1059 coefficients and 1 exponent. (Note $f_{H_2O}(T_n)$ can be either linearized into a form like these
 1060 other feedbacks or rewritten in the $(1 - \frac{\phi_{LW}(H_2O \text{ absorb})}{2j^*(T_n)})$ form.)

$$1061 \quad f_{H_2O}(T_n) \doteq \beta_1 (1/T_n)^{p_1} \approx 1 - (1 + \beta_1 (T_{2002})^{-p_1} - \beta_1 p_1 (T_{2002})^{-p_1-1} * (T_n - T_{2002})) \quad (A22)$$

$$1062 \quad f_{\alpha A}(T_n) \doteq 0.834 \left(1 + \beta_2 (T_n - T_{2002}) \right) + \frac{AC_n - AC_{2002}}{G_0^* d_{2002}} \quad (A23)$$

$$1063 \quad f_{\alpha S}(T_n) \doteq 0.909 \left(1 + \beta_3 (T_n - T_{2002}) \right) \quad (A24)$$

1065 Finally returning to the heat flux between the surface and the deeper layer of the ocean, other
 1066 researchers have modeled this $Q_{surf-deep}$ as a simple thermal conductivity γ multiplied by the
 1067 difference in deviation temperatures between the surface ($\Delta T_n - \Delta \theta_n$), with these
 1068 deviations measured relative to the pre-industrial equilibrium.

$$1069 \quad Q_{surf-deep} = \gamma(\Delta T_n - \Delta \theta_n) = \gamma * (T_n - \theta_n - T_{1850} + \theta_{1850}) \quad (A25)$$

1070 If we take $T_{1850} = 286.7K = 13.55^\circ C$ and $\theta_{1850} = 276.7K = 3.55^\circ C$, then $\zeta = 10K$. This
 1071 consistent equilibrium temperature difference exists because the ocean is temperature
 1072 stratified. We used γ from the CMIP5 reported by Geoffroy (2013) to be 0.67 ± 0.15 W/m²/K.
 1073 Estimates of γ from the CMIP6 coupled model comparison project were almost unchanged,
 1074 0.64 ± 0.14 W/m²/K (Hall and Fox-Kemper 2023). The deep ocean heat content record was
 1075 extended back from 1850-1869 by prepending zero values. Since this is an equilibrium value,
 1076 the deviation from the equilibrium deep ocean temperature $\theta_{1850} = 276.7K$ is given by the
 1077 deviation from this baseline heat content.

1078

1079 **A3: Solving for unknown β coefficients:**

1080 Following the definition of climate feedback of w as $\partial N / \partial w * dw / dT$, where N is the TOA
 1081 radiative flux (the entire EBM model), we equated the climate feedbacks of each of the three
 1082 f feedback functions and the Planck response j^* , with the values (in W/m²/K) reported in
 1083 Table 7.10 and Figure 7.10 of AR6 (Forster, Storelvmo et al. 2021).

$$1084 \quad \frac{\partial N}{\partial j^*} * \frac{dj^*}{dT_n} = -\tilde{g}_n * f_{H2O}(T_n) * 4\sigma_{sf}(T_n)^3 = -3.22 \quad (A26)$$

$$1085 \quad \frac{\partial N}{\partial f_{H2O}(T_n)} * \frac{df_{H2O}(T_n)}{dT_n} = -j^* * \tilde{g}_n * -\beta_1 p_1(T_n)^{-p_1-1} = 1.30 \quad (A27)$$

$$1086 \quad \frac{\partial N}{\partial f_{aA}(T_n)} * \frac{df_{aA}(T_n)}{dT_n} = 340 * \tilde{d}_n * f_{aS}(T_n) * 0.834 \beta_2 = 0.35 \quad (A28)$$

$$1087 \quad \frac{\partial N}{\partial f_{aS}(T_n)} * \frac{df_{aS}(T_n)}{dT_n} = 340 * \tilde{d}_n * f_{aA}(T_n) * 0.909 \beta_3 = 0.42 \quad (A29)$$

1088 Solving for the exponent by taking the ratio of the first two equations yielded $p_1=1.615$.
 1089 Furthermore, based on the CERES measurements from 2000-2005, everything to the left of
 1090 both β_2 (A13) and β_3 (A14) is the overall absorbed SW radiance of $340 * 0.707 = 240.5$ W/m²,
 1091 so $\beta_2 = 0.00136$ K⁻¹ and $\beta_3 = 0.00163$ K⁻¹.

1092 Figure 3.3 from Zhong and Haigh (2013) shows that per log10 order of magnitude of
 1093 [CO2] increase, an additional 15.45 W/m² is absorbed. However, Forster (2023), the
 1094 “greenhouse gas” absorption increases by 12.74 W/m² per log10 order of magnitude of
 1095 effective [CO2] increase (eq. A21). This measurement approximating a partial derivative was
 1096 presumably made recently, so we used the more recent 2002 temperature of ~287.5K
 1097 (14.4°C), but this choice is relatively inconsequential: $\beta_0\beta_1$ would be only 0.66% larger if the
 1098 pre-industrial temperature were used instead. In the pre-industrial climate, we assumed a
 1099 steady-state equilibrium with a constant black body temperature of 286.66K (13.6°C) and a
 1100 $\log_{10}([\text{effective CO}_2]) \approx 2.444$. This allows us to solve for β_0 and β_1 as follows:

$$1101 \quad 12.74 = \frac{\partial N}{\partial \tilde{g}_n} * \frac{d \tilde{g}_n}{d \log_{10}([\text{eCO}_2]_n)} = -\sigma_{\text{sf}}(T_n)^4 \beta_1 (T_n)^{-1.61} (-\beta_0) \quad (\text{A30})$$

$$1102 \quad 307.24 = \beta_1 \beta_0 \quad \text{using } T_{2002} = 287.5 \quad (\text{A31})$$

$$1103 \quad 0 = 340 * \tilde{d}_n * f_{\alpha_A}(T_{1850}) * f_{\alpha_S}(T_{1850}) - \sigma_{\text{sf}}(T_{1850})^4 \beta_1 (T_{1850})^{-1.61} (1 - \beta_0(2.444)) \quad (\text{A32})$$

$$1104 \quad 240.56 = \sigma_{\text{sf}}(286.7)^{2.39} (\beta_1) (1 - \beta_0(2.444)) \quad (\text{A33})$$

$$1105 \quad 5842.68 = (\beta_1) (1 - \beta_0(2.4)) \quad (\text{A34})$$

$$1106 \quad 6593.57 \approx \beta_1 \quad \text{and} \quad 0.04660 \approx \beta_0 \quad (\text{A35})$$

1107 Checking that Planck partial derivative is accurate, we obtained a value for climate sensitivity
 1108 of j^* to be -3.34 W/m²/K at current conditions and the sensitivity of f_{H_2O} to be 1.35 W/m²/K,
 1109 within the likely range of AR6. With an instantaneous doubling or quadrupling of CO₂ the
 1110 sensitivity of j^* becomes -3.30 W/m²/K or -3.22 W/m²/K respectively, matching the reported
 1111 value. Because they were defined to have proportional climate sensitivities, f_{H_2O} exactly
 1112 matches AR6 in a 4xCO₂ scenario, with 1.30 W/m²/K.

Values of Energy Balance Model (n=2002)

1113

1114 Fig. A2: Diagram with energy fluxes, temperatures, and total ocean heat content for the blind
 1115 run of energy balance model in 2002 (when many of the reflectivity values were first
 1116 measured by satellite).

1117

1118 **A4: Differentiating to Find the Jacobian Matrix**

1119 This yielded a blind energy-balance model with good skill at predicting the GMST
 1120 (orange dashed line in Fig. 2), $R^2 = 0.902$. Rewriting the overall model with β coefficients,

$$1121 \quad T_{n+1} = T_n + \frac{257.9 * 9.068}{17 (AOD_n + 9.73)} \left(1 + \beta_2 (T_n - 287.5) + \frac{AC_n - AC_{2002}}{G_0^* \bar{d}_{2002} 0.834} \right) \left(1 + \beta_3 (T_n - 287.5) \right)$$

$$1122 \quad - \frac{\sigma_{sf} \beta_1}{C_{surf}} (T_n)^{2.39} (1 - \beta_0 \log_{10} ([eCO_2]_n)) - \frac{\gamma}{C_{surf}} (T_n - \theta_n - 10) \quad (A36)$$

$$1123 \quad \text{Derivatives of } \theta_n: \frac{\partial \theta_n}{\partial H_n} = 1/C_{deep} \quad (A9a) \quad \frac{\partial \theta_n}{\partial T_n} = C_{surf0}/C_{deep} \quad (A9b)$$

$$1124 \quad \frac{\partial T_{n+1}}{\partial T_n} = 1 + \frac{137.6}{AOD_n + 9.73} \left(\beta_2 + \beta_3 + 2\beta_2\beta_3 (T_n - 287.5) + \beta_3 \frac{\bar{q}_n - \bar{q}_{2002}}{G_0^* \bar{d}_{2002} 0.834} \right)$$

$$1125 \quad - \frac{2.39 \sigma_{sf} \beta_1}{C_{surf}} (T_n)^{1.39} (1 - \beta_0 \log_{10} ([eCO_2]_n)) - \frac{\gamma}{C_{surf}} (1 - C_{surf0}/C_{deep}) \quad (A37)$$

$$1126 \quad \frac{\partial T_{n+1}}{\partial H_n} = \frac{\gamma}{C_{surf}} * \frac{\partial \theta_n}{\partial H_n} = \frac{\gamma}{C_{surf} C_{deep}} \quad (A38)$$

1127 The ocean heat content update equation ($R^2 = 0.907$) and related partial derivatives are:

$$1128 \quad H_{n+1} = (T_{n+1} - T_{1850}) * C_{surf0} + \gamma * (T_n - \theta_n - \zeta) + (\theta_n - \theta_{1850}) * C_{deep} \quad (A39)$$

$$1129 \quad \frac{\partial H_{n+1}}{\partial H_n} = C_{\text{surf0}} \frac{\partial T_{n+1}}{\partial H_n} + \gamma * \left(0 - \frac{\partial \theta_n}{\partial H_n} \right) + C_{\text{deep}} \frac{\partial \theta_n}{\partial H_n} = \frac{\gamma}{C_{\text{deep}}} * \left(\frac{C_{\text{surf0}}}{C_{\text{surf}}} - 1 \right) + 1 \quad (\text{A40})$$

$$1130 \quad \frac{\partial H_{n+1}}{\partial T_n} = C_{\text{surf0}} * \frac{\partial T_{n+1}}{\partial T_n} + \gamma * \left(1 - \frac{C_{\text{surf0}}}{C_{\text{deep}}} \right) + C_{\text{surf0}} \quad (\text{A41})$$

1131

1132

Appendix B: Generation of Volcanic Eruption Samplings

1133
 1134 As can be appreciated in Fig. B1a, long periods of no major volcanic eruptions (for
 1135 instance 1935-1960) alternated with periods of many eruptions occurring in rapid succession
 1136 (1883-1914, 1960-1994). Perhaps this observed pattern has some relation to magma or
 1137 tectonic dynamics, but it prevented one Poisson distribution from describing the data well.

1138
 1139 Fig. B1: Comparison of Historical Volcanic Eruptions (B1a) with Simulated Volcanic
 1140 Eruptions (B1b), generated from a combination of several probability distributions.
 1141
 1142 Eruptions that occurred within 3 years were indistinguishable in the historical dataset,
 1143 so the minimum time interval between simulated volcanic eruptions was 2.6 years plus a
 1144 sample (Table B1) from the exponential mixture model i_n (Okada, Yamanishi et al. 2020).
 1145 These intervals were rounded to integers. Similarly, the size of each volcanic eruption h_n was
 1146 approximated using another shifted exponential distribution. The preceding year and two
 1147 years following the eruption peak were positive fractions of the maximum aerosol optical
 1148 depth, with gaussian blur. Similarly, non-volcanic years were positive gaussian noise (Table
 1149 B2). Fig. B1b shows a sample from this combined generating function.

Exponential Distribution	Rand. Var.	Scale (units)	P(if mixture)
Interval Between: $\text{round}(i_{n,0} + 2.6)$	$i_{n,0} \sim \text{Exp}$	2.263 (years)	88.9%
Interval Between: $\text{round}(i_{n,1} + 2.6)$	$i_{n,1} \sim \text{Exp}$	24.2 (years)	11.1%

Peak Size: $AOD_n = h_n + 0.0082$	$h_n \sim \text{Exp}$	0.0339 (m)	
-----------------------------------	-----------------------	------------	--

1150 Table B1. Exponential Parameters of Volcano Generating Function. This generating function
1151 starts with a list of zero values for all AOD_n , and first samples several of these n years to be
1152 major volcanic eruptions. “Interval Between” refers to the interval in years between two
1153 successive major volcanic eruptions.
1154

Gaussian Distribution	Rand. Var.	Mean μ (units)	Std Dev σ
Pre-Peak: $AOD_{n-1} = a_{-1} * E_n$	$a_{-1} \sim \text{Norm} > 0$	0.51	0.25
Post-Peak 1: $AOD_{n+1} = a_1 * E_n$	$a_1 \sim \text{Norm} > 0$	0.61	0.16
Post-Peak 2: $AOD_{n+2} = a_2 * E_n$	$a_2 \sim \text{Norm} > 0$	0.32	0.16
Other Years: $AOD_n = a_0$	$a_0 \sim \text{Norm} > 0$	0.00371 (m)	0.00286 (m)

1155 Table B2. Gaussian Parameters of Volcano Generating Function. These distributions are
1156 sampled after the major eruptions have already been filled in by the exponential distributions
1157 in Table B1.
1158

1159 **Appendix C: Glossary of Mathematical Symbols and Notation**

Symbol	Meaning	Context	Units
p	Probability of the observed result for a particular hypothesis test (e.g. that the slope is positive)	Statistics	(0,1)
R^2	Coefficient of determination: fraction of variance explained by a particular model	Statistics	(0,1)
σ	Standard deviation ($\sqrt{\text{Variance}}$)	Statistics	(K)
$\text{Cov}()$	Covariance of a random vector (here length 2)	Statistics	2x2 (K ²)
n, k	Time index, time step	KF, EBM	year
T_n	GMST surface temperature climate state, idealized	EBM-KF	K
θ_n	Deep ocean potential temperature state, idealized	EBM-KF	K
H_n	Ocean heat content anomaly	EBM-KF	zJ
$u_n = [CO_2]_n, AOD_n$	Time-varying concentrations in the atmosphere	EBM	ppm, \emptyset
$[\tilde{T}_{n+1}, \tilde{\theta}_{n+1}] = F(\tilde{T}_n, \tilde{\theta}_n, u_n)$	Blind energy balance model, which is entirely deterministic based on prior climate state	EBM	K

$\Phi_n = \frac{\partial \mathbf{F}(\mathbf{x}; u_n)}{\partial \mathbf{x}} \Big _{\mathbf{x}=\hat{\mathbf{x}}_{n-1}}$	Linearized tensor derivative of the (blind) EBM model	EBM-KF	2x2 \emptyset
$\mathbf{x}_n = [T_n, \theta_n]$	Idealized true climate state, with dynamic model noise	EBM -KF	[K,K]
$\hat{\mathbf{x}}_n = [\hat{T}_n, \hat{\theta}_n]$	Estimate of the underlying climate state	EBM -KF	[K,K]
$\mathbf{y}_n = [Y_n, \psi_n]$	Measurements with noise of the climate state, from HadCRUT5 and Zanna 2019.	EBM -KF	[K,K]
$\mathbf{Q} = \text{COV}[w_n]$	Dynamic model error and model covariance matrix	KF	2x2 (K^2)
$\mathbf{R} = \text{COV}[v_n]$	Measurement error and measurement covariance matrix	KF	2x2 (K^2)
${}_{30}\bar{\mathbf{Y}}_n$ ${}_{30}\bar{\mathbf{T}}_n$	30-year running mean of temperature (or GMST) measurements, undefined before 1865 or after 2008	Prior climate methods	[K,K] K
$\mathbf{R}_n = \mathbf{R}_{\text{var}}(n) + \mathbf{R}_{\text{const}}$ $\mathbf{Q} = \mathbf{R}_{\text{const}}/30$	Actual covariance matrices used EBM_KF, defined to mimic the statistics of the 30-year running mean	EBM-KF	2x2 (K^2)
$\hat{\mathbf{x}}_{n n-1}$ $\mathbf{P}_{n n-1}$	KF a priori estimated state projection and state variance projection (before new measurement)	KF	[K,K] 2x2 (K^2)
\mathbf{c}_n ; \mathbf{S}_n	Innovation residual, innovation covariance	KF	[K,K] 2x2 (K^2)
\mathbf{K}_n	Kalman gain: weight on innovation to correct state	KF	2x2 \emptyset
$\hat{\mathbf{x}}_n$ \mathbf{P}_n	KF a posteriori estimated state projection and state variance (after measurement)	KF	[K,K] 2x2 (K^2)
$\hat{\mathbf{K}}_n$, $\hat{\mathbf{x}}_n$, $\hat{\mathbf{P}}_n$	RTS re-estimated Kalman gain, state estimate, and state covariance, following backward sweep	RTS	as above
γ	Thermal conductivity between layers of the ocean	EBM	W/m ² /K

ϕ_{SW}, ϕ_{LW}	Net radiative fluxes (shortwave and longwave) at the top of the atmosphere	EBM	W
$\Delta Energy_{surf}$ Q_{surf_deep}	Net heat flow into the surface and deep ocean layers respectively	EBM	W
$C_{surf} ; C_{deep}$	Heat capacities of the surface and deep layers	EBM	$\frac{W (year)}{m^2 K}$
$G_0^*, j^*(T_n)$	Sources of shortwave (total solar radiance) and longwave (blackbody or Planck feedback)	EBM	W/m ²
\tilde{d}_n, \tilde{g}_n	Prescribed, time-varying attenuations from atmospheric dust and longwave radiation respectively	EBM	∅
$f_{aA}(T_n) * f_{aS}(T_n), f_{H2O}(T_n)$	Attenuations due to albedo of the atmosphere, albedo of the surface, and longwave absorbing water vapor (all with feedback from T_n)	EBM	∅
ζ	Equilibrium temperature difference between the surface and deep ocean.	EBN	K
σ_{sf}	Stefan-Boltzman constant = $5.670 \cdot 10^{-8}$	EBM	Wm ² K ⁻⁴
β_0	Solved coefficient on $\log_{10}([CO_2]_n)$ within a sequential filter atmosphere approximation	EBM	∅
β_1, p_1	Solved coefficient and exponent for the $f_{H2O}(T_n)$ water vapor feedback on longwave	EBM	∅
β_2, β_3	Solved coefficients for $f_{aA}(T_n) * f_{aS}(T_n)$, atmosphere and surface albedo feedbacks.	EBM	∅
$i_{n,0} i_{n,1}$	Exponential mixture random variables to determine the interval between major eruptions	Volcanoes	years
h_n	Exponential random variable to determine size of a particular major eruption	Volcanoes	∅ (AOD)

a ₋₁ , a ₁ , a ₂ , a ₀	Truncated gaussian distributions to determine the atmospheric optical depth in eruption-adjacent and non-eruption years.	Volcanoes	∅ (AOD)
--	--	-----------	------------
